Probably the new species result from alkaline oxidation of cysteine residues, linking adjacent β -lactoglobulin molecules by a disulphide bond. The similarity of heat- and alkali-induced aggregation is now being investigated. The foregoing results emphasize that β -lactoglobulin or whey protein solutions should always be freshly prepared for routine electrophoretic examination and not stored in alkaline solution.

I thank Mr. M. Rogers for his help.

Haemoglobin Polymorphism in the Cod (*Gadus morrhua*): a Single Peptide Difference

HAEMOGLOBIN of the cod (*Gadus morrhua*), when submitted to agar-gel electrophoresis at pH 7.3, shows a clear polymorphism.

Using this technique Sick¹ showed the existence of three patterns (Fig. 1) suggesting a single gene control for the fast bands Hb I1 and Hb I2. Furthermore, he found the

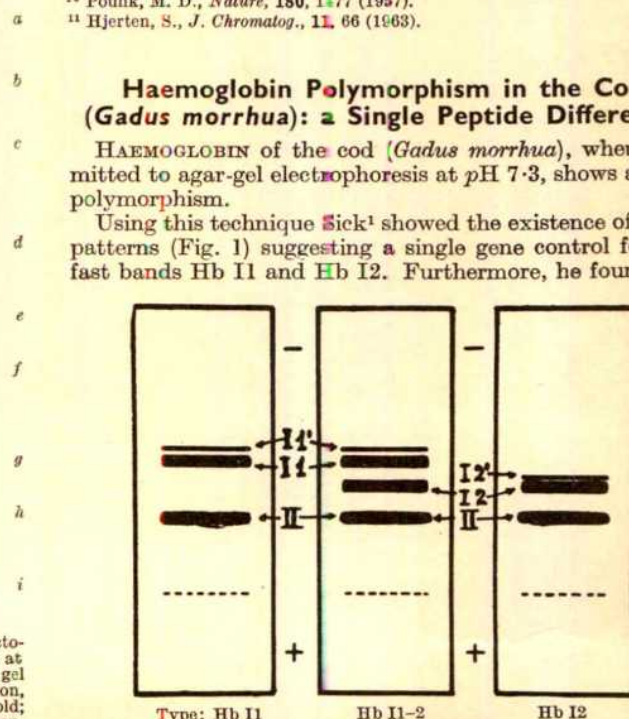

Fig. 1. Patterns showing progressive aggregation of a 1 per cent β -lactoglobulins-A, -B or -A/B mixture on storage in tris buffer (pH 8.7) at 2° C. Disc electrophoresis was performed in 11 per cent acrylamide gel rods (details given in text). a, β -A solution, fresh made; b, β -B solution, fresh made; c, β -A/B solution, fresh made; d, β -A solution, 1 day old; e, β -B solution, 1 day old; f, β -A/B solution, 1 day old; g, β -A solution, 7 days old; h, β -B solution, 7 days old; i, β -A/B solution, 7 days old. The sample application point is at the left-hand side of the photographs.

Fig. 1. Tracings of patterns of cod haemoglobin subjected to agar-gel electrophoresis, phosphate buffer 0.02 M, pH 7.3

change in position is indeed small, the substitution, if any, should involve two neutral amino-acids. A preliminary analysis seems to suggest that this is so. (2) What is the relationship between the aforementioned 'core' peptides and the 'extra' one in Hb II chymotryptic digest? The answers will come only from sequence analysis of the free peptides.

This work was carried out in the Laboratory of the Department of Paediatrics of the University of Groningen. We thank Prof. J. P. H. Jonxis for his help and advice, and Miss du Vigny, Royal Institute for Fishery Research, Muiden, Holland, for the blood samples.

Factors affecting the Amount and Composition of the Serum Seromucoid Fraction

THE glycoprotein-rich seromucoid fraction¹ is isolated by first precipitating most serum proteins with perchloric acid—seromucoid being precipitated from the filtrate with phosphotungstic acid. The solubility of certain glycoproteins in perchloric acid is assumed due to covalently bound hexose, hexosamine, fucose and sialic acid residues. Thus, seromucoid contains perchloric acid-soluble rosomucoid, Zn- α_2 -glycoprotein, haemopexin, the haptoglobins and 3.5 S α_1 -glycoprotein² with total carbohydrate and sialic acid contents above 8.0 and 3.3 per cent respectively. Insoluble glycoproteins, absent from seromucoid, include α_2 -macroglobulins, ceruloplasmin and transferrin with less carbohydrate content. Seromucoid also contains small amounts of co-precipitated albumin, pre-albumin and γ -globulins which, when pure, are perchloric acid-insoluble.

If a causal relationship were to exist between glycoprotein solubility and carbohydrate content, then removal of carbohydrate residues from glycoproteins should decrease their solubility in perchloric acid and lead to decreased seromucoid precipitation. Since terminally-bound sialic acid residues on glycoproteins can be selectively removed by neuraminidase, the effect of this carbohydrate on glycoprotein solubility in 0.6 M perchloric acid has been investigated.

Normal human serum, containing 60 mg glycoprotein-bound sialic acid/100 ml., was used; the seromucoid-level was 103 and 16.7 mg/100 ml., expressed in terms of protein and hexose contents respectively. Seromucoid was precipitated³ before and after treatment of serum with neuraminidase (*E.C.* 3.2.1.18), the source of which was receptor destroying enzyme (R.D.E.) from *Vibrio cholerae* (Burroughs Wellcome and Co., London). To 10 ml. of serum were added 10 ml. of 0.2 M acetate buffer (pH 5.5, containing 10^{-2} M calcium acetate) and 3 ml. 0.1 N hydrochloric acid, the final pH being 5.5. To 4-ml. aliquots were added 2 ml. R.D.E. These mixtures were incubated at 37°. At varying time intervals (0–24 h) 24.8 ml. 0.9 per cent sodium chloride was added to each mixture, and free sialic acid estimated in 0.2 ml. aliquots⁴. To 30 ml. of the remaining mixture were added 14.96 ml. of 1.8 M perchloric acid; the precipitated proteins were separated by filtration through No. 50 Whatman filter paper after 10 min. The seromucoid fraction was then precipitated from 32 ml. of the filtrate with 6.4 ml. of phosphotungstic acid reagent (5 per cent, w/v, in 2 N hydrochloric acid), and measured turbidimetrically at 400 m μ after standing

for 15 min. The fraction was then centrifuged down, washed with 10 ml. 95 per cent (v/v) ethanol, dissolved in 4 ml. 0.1 N sodium hydroxide, and estimated for hexose and protein⁵. As is seen in Fig. 1, the enzymatic removal of sialic acid from serum glycoproteins was accompanied by decreased seromucoid precipitation. Sialic acid residues evidently confer hydropathic properties on some serum glycoproteins, their removal decreasing glycoprotein solubility in perchloric acid, thus decreasing the amount of seromucoid precipitated from the perchloric acid filtrate by phosphotungstic acid. This effect was particularly noticeable when seromucoid was estimated turbidimetrically⁶.

Glycoproteins with decreased perchloric acid-solubility following sialic acid removal are probably relatively low in carbohydrate content since purified orosomucoid, containing 40 and 12 per cent total carbohydrate and sialic acid respectively, remained perchloric acid-soluble after the complete removal of sialic acid, presumably because the amounts of hexose and hexosamine remaining were sufficiently high to maintain solubility.

The presence in seromucoid of serum proteins which are normally perchloric acid-insoluble may result from the 'protective' properties of glycoproteins⁷. The protective effect of seromucoid on the precipitation of albumin by perchloric acid was therefore investigated, using seromucoid (containing 4 per cent sialic acid) isolated from normal serum by the precipitation method described in Fig. 1. To five tubes containing albumin (0.8 mg), dissolved in 0.1 ml. 0.9 per cent sodium chloride, were added increasing amounts of seromucoid (0–1 mg), dissolved in 0.1 ml. 0.05 N sodium hydroxide. To each tube was added 3 ml. phosphate buffer (0.2 M, pH 7.4) followed by 1.6 ml. 1.8 M perchloric acid; the albumin precipitated was measured turbidimetrically at 400 m μ after 10 min. From Fig. 2, it is evident that seromucoid protected albumin from precipitation by perchloric acid.

Serum glycoproteins function as protective colloids, probably enabling small amounts of normally insoluble substances, such as albumin, pre-albumin and γ -globulins, to remain soluble on the addition to serum of perchloric acid, addition of phosphotungstic acid to perchloric acid filtrates causing them to precipitate with the seromucoid fraction. The presence of these normally insoluble substances in seromucoid, therefore, depends on the amount and protective efficiency of serum glycoproteins, which may vary in pathological conditions.

Factors affecting seromucoid precipitation are of some importance, since these levels vary in disease⁸ and are claimed to be of value in cancer diagnosis and in assessing response to treatment⁹. This is particularly relevant in

Fig. 1. Decreased precipitation of seromucoid following the removal of sialic acid from serum glycoproteins. Seromucoid-levels were determined turbidimetrically (○), and by estimation of seromucoid protein (△) and hexose (□) contents. Results are expressed as the percentage decrease in the seromucoid fraction following the progressive enzymatic removal of sialic acid from serum glycoproteins.

Fig. 2. Protective effect of seromucoid on the precipitation of albumin by 0.6 M perchloric acid. Albumin was estimated turbidimetrically at 400 mμ.

view of recent reports that orosomucoid, isolated from the serum of patients with certain diseases, is sialic acid-deficient^{10,11}. If other serum glycoproteins also lack sialic acid, low seromucoid-levels may result due to decreased glycoprotein solubility in perchloric acid.

Whether the low seromucoid-levels observed in patients with parenchymatous liver diseases¹² result from defective synthesis in the liver¹³ producing sialic acid-deficient, perchloric acid-insoluble glycoproteins must await further knowledge of the composition of these substances in abnormal sera, the perchloric acid-solubility and protective properties of which appear dependent on the nature and amount of covalently bound carbohydrates.

PHYSIOLOGY

Tubular Site of Urate Secretion in the Rabbit

In the rabbit a pronounced secretion of urate during infusion of urate has been shown¹. In the Dalmatian dog secretion of urate may be readily demonstrated, while re-absorption of urate prevails in the mongrel (that is, non-Dalmatian) dog. A proximal re-absorption of urate in the mongrel dog has consistently been observed by the stop-flow method²⁻⁴, whereas secretion has been found at this site in the Dalmatian dog^{2,4}. Yü *et al.*⁴ have suggested that a weak secretion of urate also occurs in the distal tubule. We have examined the site of urate secretion in the rabbit by the stop-flow method and with the aid of labelled urate.

The experiments were conducted on male animals anaesthetized intravenously with 45 mg 'Nembutal'. Respiration was maintained throughout the experiment by a respiration pump, and polyethylene catheters were inserted in the jugular vein and carotid artery on one side, and in the right ureter. The stop-flow procedure was similar to the method of Malvin *et al.*⁵. An infusion containing creatinine (0.5 per cent), mannitol (5 per cent) and in some instances urate (0.1 per cent), dissolved in physiological saline, was given through the venous cannula at a rate of 2.3 ml./min. One minute before releasing the occlusion, a solution containing 250 mμ inulin and either 50 mg urate or 15 μc. ⁸⁻¹⁴C-urate was injected over a period of 30 sec. Urate was analysed by an enzymatic method⁶. Radioactivity was measured by a Packard 'Tri-Carb' scintillation counter after dissolving 50 μl. of urine in 5 ml. of Bray's mixture⁷.

Fig. 1 gives the results of an experiment in which 50 mg of urate was injected post-occlusively. The concentration of Na⁺, urate, and inulin has been plotted as function of the amount of urine collected after the stop-flow period. Corresponding to the dip in the Na⁺ curve (which marks the distal part of the nephron), the urate concentration increases sharply. The concentration of urate reaches a peak value after collection of c. 4 ml. of urine. It can be seen from Fig. 1 that an increase in urate concentration occurs just before the appearance of inulin (the inulin indicates formation of new glomerular filtrate after the stop-flow period). The experiment thus shows a pronounced permeation of urate across the proximal tubules.

In the experiment shown in Fig. 2 urate was infused during the whole experiment, and probenecid—which inhibits urate secretion in the rabbit—was administered intravenously in a dose of 100 mg/kg prior to the stop-flow period. At the end of the occlusion period labelled urate was infused along with inulin. It appears from Fig. 2 that radioactivity in samples originating from the distal tubule is very small. An increased number of counts is

Fig. 1. The stop-flow pattern after injection of 50 mg urate and 250 mg inulin post-occlusively.

Fig. 2. The stop-flow pattern after injection of 15 μc. urate post-occlusively. Urate was infused during the whole experiment, and 100 mg probenecid was given intravenously prior to the stop-flow period.

served concomitantly with the excretion of inulin in the urine. It is seen that the rise in the 'radioactivity rve' is only slightly greater than that for the inulin rve. On the basis of these findings it may be concluded that probenecid strongly inhibits an active transport of urate from the plasma to the tubular fluid in the proximal tubules.

The two curves on the left side of the diagram show a lot of the U/P values of chemically determined urate and creatinine. A pronounced rise in the U/P values for urate and creatinine is observed in samples from the distal tubule. Creatinine may be used as an approximate measure of glomerular filtration rate in the rabbit, and the increase in the distal concentrations of creatinine during stop-flow conditions is due to re-absorption of water following the re-absorption of Na^+ . The U/P values for urate are a little below the corresponding ones for creatinine. A similar relationship between the excretion of urate and creatinine after administration of probenecid is found under free-flow conditions, and so it must be concluded that the re-absorption of water in the distal part of the nephron accounts entirely for the increased concentration of urate during the stop-flow period. No net transport of urate can be demonstrated, and since the distal tubule is practically impermeable to the radioactive urate, infused during the occlusion, urate has either moved out of or into the tubular fluid of the distal part of the nephron.

The experiments thus show that the secretion of urate in the rabbit is localized to the proximal tubules and may be almost completely inhibited by administration of probenecid. In contrast, the distal part of the nephron is virtually impermeable to urate.

Response of Melanocytes of Dermis and Epidermis to Lightening Agents

THE frog has been prominent in investigations of hormonal control of human skin colour. The excised skin of *Rana pipiens* is sensitive to α -melanocyte stimulating hormone (α -MSH); less than 10^{-11} g added to 20 ml. of Ringer's solution containing the specimen produces darkening. The responsiveness of frog skin to MSH led to its use in an *in vitro* frog skin assay¹ which played an important part in the isolation and identification of α - and β -MSH². These peptides when administered systemically darken human skin^{3,4}. The use of the frog skin assay led also to the isolation of an indole, melatonin, which is synthesized in the pineal⁵. When added to frog skin previously darkened with MSH, melatonin was found to be a very potent lightening agent. Other compounds sharing this ability to lighten MSH darkened frog skin are nor-epinephrine and acetylcholine⁶.

It is the purpose of this communication to contrast the effect of these lightening agents on dermal and epidermal melanocytes.

Frogs were decapitated, the skins removed and washed in four changes of frog-Ringer's solution for 3 h before use. Skins were mounted on rings, placed in beakers containing

20 ml. Ringer's solution and reflectance (skin colour) was measured with a 'Photovolt' model 610 reflectance meter as described¹.

Specimens were fixed in 10 per cent formol-saline for 30 min, then incubated with 0.5 per cent trypsin (1 : 250 Difco) for 10 min at 30°. The specimen was then rinsed and, under observation with a dissecting microscope, the epidermis was peeled from the dermis.

Examination of the epidermis in an area of a dark skin marking revealed contracted melanocytes with a rare projection (Fig. 1). Five units of MSH, added to the specimen 60 min before fixation, effected the expansion of epidermal melanocytes to arborized, dendritic forms with long-branched processes, morphologically indistinguishable from mammalian melanocytes (Fig. 2).

Melatonin (2×10^{-3} μ g) added to a skin darkened for 60 min with 5 units of MSH produced almost complete lightening (increased reflectance) to a pre-MSH treatment value within 20 min. The epidermal melanocytes (Fig. 3), however, were identical with epidermal melanocytes of the MSH-darkened skin.

This lack of response of frog epidermal melanocytes to melatonin is consistent with its lack of effect on human skin colour⁷ and guinea-pig epidermal melanocytes⁸.

Dermal melanocytes from the preceding specimens were found to be contracted and compact before the addition of

Fig. 1. Epidermis from skin of *Rana pipiens* which has been fixed and separated from dermis as indicated in text. The specimen was cleared in xylene and mounted on a glass slide. The skin was washed for 3 h in Ringer's solution before fixation. The melanocytes are dense and contracted. A rare dendritic process is filled with melanin granules. Notice the extra-melanocytic melanin granules in the epidermis. ($\times 468$)

Fig. 2. Epidermis from a specimen exposed to 5 units of MSH for 60 min before fixation. The cell bodies are less dense than in Fig. 1. Melanin granules fill the delicate dendritic processes. ($\times 468$)

Fig. 3. Epidermis from a specimen exposed to 5 units of MSH for 60 min to which melatonin 2×10^{-3} μ g was then added 20 min before fixation. The epidermal melanocytes are identical with those fixed in formalin before treatment with melatonin (Fig. 2). ($\times 468$)

MSH. MSH effected the expansion of dermal melanocytes to stellate, dense forms. The addition of melatonin to the specimen darkened with MSH caused the dermal melanocytes to contract to the pre-MSH state.

Two other agents, acetylcholine and norepinephrine, are powerful lightening agents for MSH-darkened frog skin⁶. Acetylcholine (5×10^{-3} M) or norepinephrine (5×10^{-4} M) when added to specimens darkened with MSH produced 90 per cent lightening (increased reflectance) and contraction of the dermal melanocytes to the pre-MSH state. Neither acetylcholine nor norepinephrine, however, caused any morphological alteration in epidermal melanocytes previously expanded by MSH.

It is apparent from these observations that dermal melanocytes have a qualitatively different response to melatonin, acetylcholine and norepinephrine from epidermal melanocytes. Both populations of melanocytes respond similarly with melanin granule dispersion to MSH⁹.

Role of the Gut in Synthesizing the Protein Component of Low-density (Beta) Lipoprotein

SYNTHESIS of the protein component of human low-density lipoprotein (LDL), and elaboration of these lipoproteins from lipid and protein constituents, are regarded as occurring in the liver¹. In the Bassen-Kornzweig syndrome, absence of LDL is associated with steatorrhea and changes in small-gut histology². Salt *et al.*³ have speculated that the gut wall might be one site of lipoprotein synthesis. Isselbacher and Budz⁴ have shown that rat intestinal mucosa does synthesize lipoproteins. In rats, cholesterol synthesis occurs in the gut⁵. In human beings, 70 per cent of plasma cholesterol is carried by

LDL, and if gut wall synthesis of cholesterol is shown occur in man, the possibility again arises that a proportion of human LDL might also be elaborated in the intestinal mucosa. LDL newly synthesized by the gut could reach the general circulation via lacteal-lymphatic pathway or directly through the portal venous system.

The opportunity to investigate possible synthesis and transport of LDL by the lymphatic pathway arose in two patients with chyluria secondary to filarial obstructive of upper abdominal and thoracic lymphatics. Lymph angiography in these patients had revealed free communication between distended lymphatics in the upper abdomen, including the area occupied by the base of the small gut mesentery, and the right renal pelvis. Proteinuria in the two patients averaged 13.0 g and 5.0 g a day respectively. This total included approximately 800 mg and 300 mg a day of LDL, determined by gel-diffusion precipitin assay⁶, and by dextran sulphate precipitation.

Turnover of labelled LDL was followed in these patients by a method previously reported⁸. Total LDL was isolated from the serum of each patient, labelled with iodine-125 in the peptide component, and returned to the patient by intravenous injection. Serum LDL was assayed in duplicate by dextran sulphate precipitation and the concentration of LDL in urine measured by modified procedure using large volumes of urine and additional Ca^{++} . Specific activities were then calculated for plasma and for urine on the assumption that a radioactivity entering a trichloroacetic acid precipitate was associated with LDL. Data from the turnover investigations are shown in Table 1.

During the first 3 h of each investigation, a diuresis was produced by oral intake of fluid, including milk. In both patients, free radioiodide was present in urine passed 20 min after the intravenous injection, but protein-bound radioactivity was first detected in urine formed after 90 min in both patients. This interval of 90 min agreed with the time of appearance of T_{1824} -albumin in urine following intravenous injection of 6.78 mg of Evans blue into these two patients as a separate investigation, and contrasted with the rapid appearance of T_{1824} -albumin in patients with nephrotic syndrome. The time-courses for specific activity of plasma and urine are shown in Fig. 1. Specific activity figures for urine samples are plotted at the midpoint of the successive collection periods, which were short early in the investigations and over 24 h periods in the latter stages. Plasma specific activity declined steadily during the investigation. Urinary specific activity rose, during the 4-12-h (overnight) collection period, to reach a maximum value of the same order as that of the plasma, and then declined in parallel with plasma specific activity.

Fig. 1. Specific activity of ^{125}I -LDL in serum and urine of the two patients, expressed as counts per mg of total LDL in 5-ml. quantities of serum or urine. 24-h urine collections were incomplete in subject 1 over the interval 2.7-6.7 days. ●, Serum; ○, urine

Ratio 24 h 125 I excretion to mean plasma radioactivity (ref. 12).

U/P ratio recalculated, after correction for protein bound 125 I (125 I-LDL) in urine; that is, using only free 125 I excretion.

Calculated from uncorrected U/P ratio.

Calculated from corrected U/P ratio.

From multi-compartmental analysis by method of Matthews (ref. 12).

Turnover investigations have revealed a small extra-vascular distribution of LDL peptide in human subjects^{9,10}. In animals there is evidence for transfer of LDL from plasma to hepatic lymph¹¹. Human abdominal lymphatics may therefore contain some LDL from hepatic lymph besides transporting LDL which has passed to the extravascular compartment from blood capillaries. During a 125 I-LDL investigation, the fall in specific activity of plasma LDL is due to catabolism of labelled LDL with immediate excretion of iodine-125, and dilution of the remaining 125 I-LDL by newly synthesized, unlabelled LDL. Regardless of catabolism, LDL returning to the blood vascular compartment via abdominal lymphatics would be expected to show the same specific activity as plasma unless newly synthesized apoprotein was added to LDL in the lymphatics from gut tissues or possibly from the liver.

In our two patients specific activity in abdominal lymph over 4–12 h to equal that of plasma, and then maintained this equilibrium over successive 24-h periods. This finding argues against entry of newly synthesized LDL peptide into abdominal lymphatics. The results recorded here do not exclude LDL elaboration by the gut with direct passage of newly synthesized lipoprotein into the portal venous system. This possibility could be explored by the 125 I-LDL technique only if portal venous blood could be sampled over an adequate period and its specific activity compared with that of peripheral blood.

Evidence for Pre-synaptic Inhibition in the Lateral Geniculate Body

SZENTAGOTHAI¹ reported the presence of axo-axonic endings on fibres entering the lateral geniculate body from the retina. Bizzi and Brooks² have shown that in the unanaesthetized, unrestrained cat irregular groups of waves could be recorded simultaneously from the pontine

reticular formation and the lateral geniculate body during the desynchronized phase of sleep. The latter waves could no longer be recorded in the same conditions if the optic fibres were allowed to degenerate³. Recently, Andersen, Brooks, Eccles and Sears⁴ have produced evidence pointing to the existence of presynaptic inhibition in the ventrobasal thalamus on stimulation of peripheral nerves.

Since axo-axonic endings have been demonstrated in the lateral geniculate body and the experiments by Bizzi and Boller³ may be taken to indicate that the slow waves in the lateral geniculate body could be presynaptic in origin, an investigation has been carried out in order to see if there is any evidence for presynaptic inhibition in the same nucleus.

The experiments were performed on cats in which a complete transection of the brain stem immediately rostral to the exit of the trigeminal nerve had been made ('mid-pontine pre-trigeminal preparation'⁵) under ether anaesthesia. A micro-electrode was inserted into the lateral geniculate body and used to stimulate the optic fibres entering this nucleus. The antidromic response to this stimulus was recorded either from a bipolar concentric electrode inserted into the optic chiasm, or from the optic nerve after enucleation. The presence of any change in the terminal parts of the optic nerve fibres was assessed by any change in the excitability of these fibres near the microelectrode tip, and hence change in the size of the antidromic response⁶.

It has been found that after a brief tetanus to the mesencephalic reticular formation or to the visual cortex the antidromic volley recorded either from the chiasm or from the optic nerve was increased in size. Examples of the increase in excitability of the optic nerve fibres after a tetanus of 8 shocks (with an interval of 3.2 msec) had been applied to the reticular formation and visual cortex are shown in Figs. 1A and B respectively. It can be seen that the maximum increase in excitability occurred around 50 msec after the start of the tetanus and the effect of the tetanus lasted for approximately 250 msec. In addition, after stimulation of the reticular formation with a short tetanus, a negative wave could be recorded from the optic nerve, which resembled the dorsal root potential⁷. This latter wave was found to increase in size with a decrease in the body temperature of the animal, and to decrease in size with an increase in the rate of presentation of the tetanus. An example of the slow wave recorded from the optic nerve to a tetanus of 8 shocks with an interval of 3.2 msec to the mesencephalic reticular formation is shown in Fig. 1C. Often, especially at low temperature, spikes were seen to be superimposed on the summit of the slow wave; these spikes could also be recorded from the optic chiasm. The spikes may correspond to the dorsal root reflex⁸. Comparison of Figs. 1A and C shows that the increase in excitability and the slow wave of the optic nerve ran a similar time-course. That this slow wave was probably not an envelope of

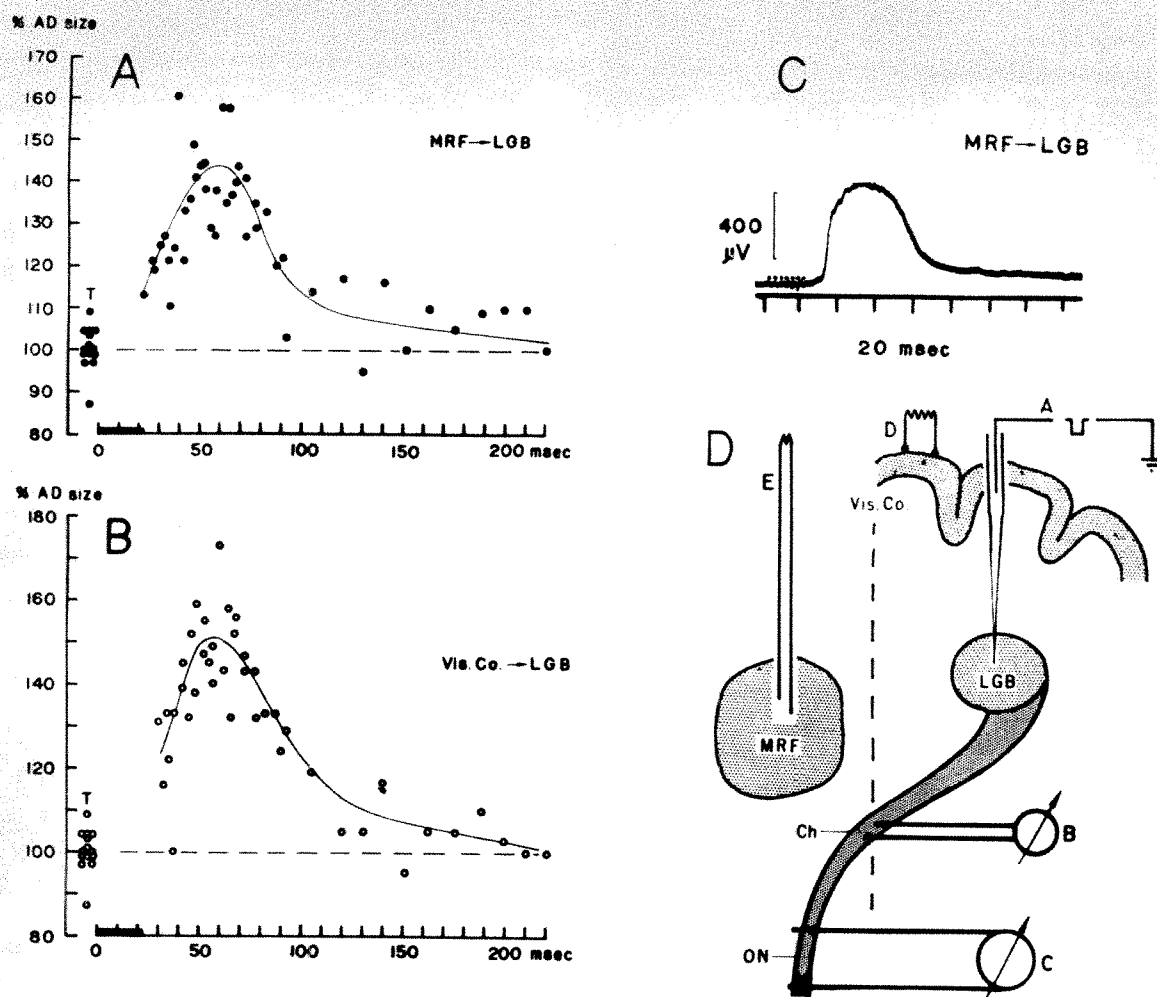

Fig. 1. Evidence for depolarization in optic nerve fibres by stimulation of the mesencephalic reticular formation and visual cortex. The experimental arrangement is shown diagrammatically in D. The micropipette used for stimulating is placed in the lateral geniculate body (LGB); the electrodes for recording the antidromic response were either in the chiasm (Ch) or on the optic nerve (ON). The graphs show the effect on the percentage amplitude of the antidromic response (AD) at various times after a brief tetanus (8 shocks with a duration of 1 msec and a separation of 3.2 msec) applied at a rate of 1/5 sec to the mesencephalic reticular formation (A) and the visual cortex (B). Each point is the average of 5 observations. The smooth curves were obtained by averaging the observations in each 50 msec period and drawing the curves through these points. Both graphs were obtained from the same animal in which the stimuli were applied alternately to the mesencephalic reticular formation and the visual cortex. The slow wave recorded monophasically from the optic nerve after stimulation of the mesencephalic reticular formation in an animal with a rectal temperature of 32° C is shown in C.

centrifugally conducted impulses has been shown by stimulating the chiasm with a single electric shock at various times during the slow wave: no evidence of occlusion between the action potential, evoked by the chiasm stimulus, and slow wave was obtained.

Using the size of the slow wave as an indicator of the effectiveness of the tetanus applied to the brain stem, it has been found that the regions giving the biggest slow wave are centred around the central tegmental tract.

The increased excitability of the optic fibres, produced by stimulation of the mesencephalic reticular formation and visual cortex, can be taken to indicate that both structures exert a presynaptic inhibitory control on the transmission through the lateral geniculate body, according to previous investigations¹¹. The possibility that the increased excitability of the optic nerve fibres may be passively produced by current flowing in a potential field due to activity elicited in nearby structures exists and cannot be overlooked. However, the fact that the time-course of the increased excitability, and of the slow wave, in the optic nerve have the long duration characteristic of the presynaptic inhibition shown in the spinal cord, and cuneate nucleus after cortical stimulation^{9,10} seems to indicate that the phenomenon we observe is due to a true presynaptic inhibition.

HAEMATOLOGY

Chronic Granulocytic Leukaemia : Demonstration of the Philadelphia Chromosome in Cultures of Spleen Cells

AN abnormal marker chromosome in chronic granulocytic leukaemia was described by Nowell and Hungerford^{1,2} and its occurrence widely confirmed³⁻⁷. This marker, the Philadelphia chromosome (Ph¹), occurs in almost all typical cases of chronic granulocytic leukaemia and appears to be an acquired abnormality specific for the disease. The Ph¹ is derived from a chromosome of pair 21 by loss of a variable proportion of the long arms.

It has been shown⁸ that in untreated chronic granulocytic leukaemia all the dividing cells in direct preparations of bone marrow are Ph¹-positive. Apparently, megakaryocytes and erythroid precursors as well as granulocyte precursors carry the Ph¹. As haematological abnormalities are usually confined to the granulocytic series, it has been suggested⁹ that the genetic material lost from the Ph¹ has immediate relevance to leucopoiesis only. It is postulated⁸ that the erythroid, granulocytic, and megakaryocytic series have a common stem cell and the original deletion to produce the Ph¹ occurs in this stem-line. However, peripheral blood cultures in untreated cases yield mixed populations of Ph¹-positive and negative cells^{4,11}. As the dividing cells in cultures of normal blood are almost certainly of lymphoid origin¹⁰, it appears that the blood lymphocytes are Ph¹-negative and therefore must originate from a separate stem-line. Apart from cells of bone marrow origin and lymphocytes in the peripheral blood, cultured subcutaneous fibroblasts have been examined for the presence of the Ph¹ chromosome with negative results³. Only in the spleen are cells of both lymphocytic and bone marrow stem-lines to be expected to occur together, and so it is particularly important to study the cytogenetics of that organ in chronic granulocytic leukaemia. To our knowledge no such investigations have been reported. We have developed a method¹² for the cytogenetic study of lymphoid tissue; this technique was applied to spleen to obtain the results here reported.

The patient was a married woman, aged twenty-nine. Chronic granulocytic leukaemia, diagnosed 24 months previously, had been treated with busulphan, splenic irradiation, 6-mercaptopurine and cyclophosphamide. Resistance to all therapy had arisen and the disease had undergone acute transformation. Splenectomy was performed for massive splenomegaly and intractable thrombocytopenia. Spleenic cell suspensions were cultured: (a) for 16 h without phytohaemagglutinin, (b) for 84 h with added phytohaemagglutinin. The chromosome count distribution was:

Chromosome No.	<45	45	46	47	48	92-93	Totals
No. of cells (a)	7	8	26	5	1	0	47
(b)	7	12	53	16	0	2	90

On analysis, the dominant cell line was diploid and Ph¹-positive. A second line with 47 chromosomes due to the presence of a second Ph¹ was also identified. Excluding technically unsuitable cells, results of analysis as regards the presence of the Ph¹ chromosome were:

	Cells analysed	Ph ¹ +	Ph ¹ ++	Ph ¹ -	Status uncertain
Preparation (a)	41	29	7	1	4
(b)	73	57	14	1	1

Thus Ph¹ negative cells accounted for only 2.4 per cent of the cells in 16-h culture and 1.4 per cent in 84-h culture. Splenic sections showed loss of normal architecture and absence of lymphocyte aggregations. A differential count of 500 cells in a splenic imprint showed 4 per cent of lymphocytes in a population of leukaemic blast cells and promyelocytes.

Thus almost all dividing cells from this patient's spleen were Ph¹ positive. This result, to be expected in the 16-h

unstimulated culture, is surprising in the 84-h culture with phytohaemagglutinin, where Ph¹-negative cells of lymphoid origin might well be prominent. Possibly these cells failed to divide; however, splenic lymphocytes have been successfully cultured in this laboratory and elsewhere¹³. The initial small number of lymphocytes relative to leukaemic blast cells might explain the rarity of Ph¹-negative mitoses, but studies have shown that in cultures with phytohaemagglutinin normal cells may outstrip leukaemic cells¹⁴⁻¹⁶. A better hypothesis is that in advanced chronic granulocytic leukaemia all splenic stem cells, possibly including lymphocytic precursors, carry the Ph¹.

The presence of two Ph¹ chromosomes per cell has previously been observed in the chronic phase of chronic granulocytic leukaemia¹⁷ and also in the phase of acute transformation¹⁸⁻²⁰, when it is more common. Further investigations of splenic cytogenetics in chronic granulocytic leukaemia during the chronic phase and after acute transformation are desirable.

Stable Messenger RNA in Nucleated Erythrocytes

THE mammalian reticulocyte is capable of synthesizing haemoglobin for many hours after its nucleus has been extruded. Since the nucleus is the site of messenger-RNA synthesis¹, these cells must be using stable messenger for continued protein synthesis. In contrast to the red blood cells of mammals, erythrocytes of lower vertebrates and invertebrates are almost always nucleated. With the nucleus present these cells could conceivably synthesize protein on short-lived messenger templates. In order to determine whether nucleated red blood cells utilize short- or long-lived messenger-RNA, representative avian and reptilian erythrocytes were investigated by stopping DNA-dependent RNA synthesis with actinomycin D and following the course of protein synthesis in the functionally 'enucleated' cells.

Reticulocytosis was produced in young chickens and in adult turtles (*Pseudemys elegans*) by repeated bleedings; 15-day chick embryo erythrocytes (about 100 per cent reticulocytes) were used with identical results. Reticulocytes in turtle blood samples numbered about 10 per cent and in chick blood about 30 per cent. The red cells were separated by centrifugation, washed, and incubated in Waymouth medium with penicillin and streptomycin in

a 5 per cent atmosphere of carbon dioxide. Chick cells were incubated at 37°, turtle cells at 30°. Parallel incubations were done with control red cells and with red cell mixtures containing 10 µg/ml. actinomycin D. Aliquots were removed at intervals, washed, and incubated for 30 min with 5 µc./ml. L-leucine-¹⁴C (sp. act. 220 mc./mM) in saline. The cells were precipitated with 5 per cent trichloroacetic acid (TCA), plated on 'Millipore' filters and counted in a gas flow counter. Each experiment was repeated at least twice. To ensure that actinomycin stopped messenger-RNA synthesis persisting in circulating cells, experiments were performed in which reticulocytes were incubated in nutrient medium with 0.5 µc./ml. uridine-¹⁴C (sp. act. 25 mc./mM) for 10 min. The culture was then divided and 10 µg/ml. actinomycin added to one portion. The synthesis of RNA (uridine counts precipitable with cold 5 per cent TCA) was shown to stop within 10 min for chick cells and within 20 min for turtle cells.

Experiments such as those in Fig. 1 demonstrated that protein synthesis continued for at least 24 h in the absence of new messenger-RNA production. The life-span of the messenger was similar in both the chicken and in the turtle erythrocytes. The results do not show that protein synthesis in these red blood cells is equivalent to haemoglobin synthesis, but haemoglobin is the major protein product of the mammalian reticulocyte², and it is likely for these cells as well.

The fact that there is long-lived messenger-RNA in the chicken and turtle erythrocytes plus the evidence of Cameron and Prescott³ that maturation of the chick erythrocyte nucleus is associated with cessation of RNA synthesis indicate that in the maturing erythrocyte the nucleus is inactive so far as transfer of genetic information is concerned.

Fig. 1. Persistence *in vitro* of protein synthesis (above) in turtle erythrocytes (incubated at 30°) and (below) in chicken erythrocytes (incubated at 37°) after stopping messenger-RNA synthesis with actinomycin D

IMMUNOLOGY

Serological Relationship between Galactans from Normal Bovine Lung and from *Mycoplasma mycoides*

A GALACTAN (pneumogalactan) isolated from bovine lung^{1,2} precipitated 28 per cent of pneumococcal polysaccharide type XIV antiserum³. This suggested that bovine polysaccharides have galactose residues of similar linkage possibly β -1:6, β -1:3 or β -1:3:6⁴, and agreed with the postulated structures of type XIV pneumococcal polysaccharide⁴ and of lung galactan².

Recently it was reported^{5,6} that a galactan was isolated from *Mycoplasma mycoides*, the causative organism of contagious bovine pleuropneumonia (CBPP). It was decided, therefore, to determine whether a serological relationship existed between the galactans from normal bovine lung and from this organism causing lung lesions in cattle.

Purified pneumogalactan was kindly supplied by Hoffman-La Roche, Inc., Nutley 10, New Jersey. Since the isolation method of pneumogalactan is not described, we extracted, with hot phenol⁷, an acetone powder of bovine lung obtained from the U.S.A., a country free of CBPP (California Corporation for Biochemical Research, 3625 Medford St., Los Angeles); this material is referred to as normal bovine lung extract. *M. mycoides* cells were used for preparation of antiserum (x') in sheep⁸. Sera from animals naturally infected with CBPP were also used (sera Nos. 21 and 42). As our attempts to produce antisera against pneumogalactan have so far failed, the results presented here are of experiments with pneumogalactan, *M. mycoides* antigens and antisera against *M. mycoides*.

Table 1 shows the results of complement-fixation, indirect haemagglutination⁹ and tube agglutination tests using *M. mycoides* antigen with immune sera and sera absorbed with excess pneumogalactan. These results show that the pneumogalactan absorbs a considerable proportion of the relevant antibodies against *M. mycoides*.

In the agar-gel precipitin test, serum against *M. mycoides* (x') gave homologous lines with hot-phenol-extracted carbohydrate from *M. mycoides*¹⁰, pneumogalactan, and normal bovine lung extract. Sera 21, 42 and x' formed precipitin lines with hot-phenol-extracted carbohydrate; after absorption with 30 mg of pneumogalactan no lines were formed with either serum 21 or 42 and only very faint lines were produced with serum x'.

Table 1. RECIPROCAL TITRES OF *M. mycoides* ANTISERA, BEFORE AND AFTER ABSORPTION WITH PNEUMOGALACTAN, AGAINST *M. mycoides* ANTIGEN

<i>M. mycoides</i> antiserum	Complement fixation	Indirect haemagglutination	Agglutination
x' before absorption	80	640	640
x' after absorption	10	80	80
'21' before absorption	80	320	80
'21' after absorption	20	80	40
'42' before absorption	160	320	320
'42' after absorption	20	80	40

Animals naturally infected with CBPP (Nos. 21 and 42) gave positive skin test reactions¹¹ with both hot-phenol-extracted carbohydrate from *M. mycoides* and pneumolactan.

The cross-reactivity of pneumogalactan and the galactan from *M. mycoides* indicates that both these polymers have the common linkages. We are now investigating the possibility that the pneumogalactan plays a part in the pathogenesis of CBPP, either in an allergic type reaction, by localizing the organisms in the lung through an antibody-antigen reaction. It would also be of interest to determine whether human lung contains a galactan which might cross-react with the pneumococcal polysaccharides. This work was partly financed by the United States of America Agency for International Development under the terms of CCTA/AID Joint Project 16 for research on contagious bovine pleuropneumonia.

RADIOBIOLOGY

Influence of Oxygen and Cysteine on the Radical State of X-irradiated Lyophilized Liver

Blyumenfel'd and Kalmanson¹ as well as Gordy² and Miyagawa³ have already reported that radicals are formed in lyophilized rat liver by ionizing radiation using electron spin resonance techniques. Moreover, Gordy and Miyagawa have shown that oxygen and cysteine, which was allowed to diffuse into the liver before freeze-drying, alter the electron spin resonance spectra. This report describes investigations on X-irradiated mouse liver. The study also includes preparations of liver in which solutions of cysteine were injected before freeze-drying. To some extent we obtained results different from those described by the foregoing authors.

Livers freshly removed from mice were frozen at 77° K in an untreated state and subsequently lyophilized. Preparations containing cysteine were obtained by injecting 0.5 ml. of a cysteine solution (300 mg cysteine-HCl/ml. H₂O) into the freshly-removed organ. Then the liver was frozen at 77° K and lyophilized. The preparations were ground (bulk volume about 330 cm³/100 g) and irradiated with X-rays (200 kV, half-value layer: 0.64 mm copper, dose-rate: 920 r./min, dose: 100 kr.) under vacuum (about 10⁻³ torr) and in air respectively at room temperature. The electron spin resonance measurements were carried out under the same conditions, with an X-band spectrometer. Technical details were as already described in a previous publication⁴.

Samples of non-irradiated liver show a signal (5×10^{16} radicals/g), which possesses the structure of an unresolved doublet. The 'blank' signal looks like the dotted spectrum

Fig. 1. Electron spin resonance spectra of X-irradiated lyophilized liver. The solid line gives the resonance of a sample irradiated and measured in vacuum, and the dotted line shows the resonance of the same sample measured 20 min later after admission of air.

Fig. 2. Electron spin resonance spectra of X-irradiated lyophilized liver treated with cysteine. The solid line gives the resonance of a sample irradiated and measured in vacuum, and the dotted line shows the resonance of the same sample measured 20 min later after admission of air.

in Fig. 1 but does not correspond with the glycylglycine-type signal⁵ because of its smaller breadth. A touch of moisture leads to a rapid decay of the blank. Irradiation of the liver preparation with and without cysteine respectively in air produces an increase of the 'blank' signal without a change of its structure.

Irradiations of the samples with and without cysteine respectively under vacuum conditions produce in both cases the same electron spin resonance spectra (compare the solid spectra in Figs. 1 and 2). The 'blank' signal is slightly increased by the irradiation and overlapped by a second broad signal. With regard to the 'blank' signal the radiation yield amounts to $G=3.0$ per 100 eV absorbed X-ray energy. The increase of the doublet by irradiation may be due to oxygen residues in the sample tube.

An admission of air to the substances irradiated under vacuum immediately leads to a change of the electron spin resonance spectra. The alteration produces somewhat different spectra in the samples with and without cysteine (see dotted spectra in Figs. 1 and 2). In both cases the broad signal is quenched and at the same time the doublet is increased. This process continues for some hours after admission of air, because the air has to penetrate the whole sample by diffusion. Immediately after admission of air only about 80 per cent of the initial radical concentration can be measured. In the preparation with cysteine the increase of the doublet is not so large as in that without cysteine. On the other hand, an additional signal is formed in the region of lower magnetic field strength. This may be due to a sulphur radical, although it is not the typical 'cysteine-cystine-spectrum'.

Warming the irradiated sample in the evacuated state to 353° K for 10 min will only quench the broad signal; the signal height of the doublet is not altered all the time.

Only if the sample is stored for several hours at this high temperature does the radical concentration of the doublet also decrease.

These investigations show that atmospheric oxygen is able to induce a radical shift without external energy feed. Similarly, we have also found a transposition of X-ray-induced radicals from a carbon to a sulphur atom in a dimeric form of homocysteine-thiolactone, in experiments which we hope to report soon.

'Cell Killing' in Radiobiology

ONE of the most significant advances in cellular radiobiology was the development by Puck and Marcus¹ of a technique by means of which the survival from irradiation of animal cells in culture was placed on a quantitative basis. Survival has usually been expressed arbitrarily as the ability of an irradiated cell to produce, over a 10–20-day period, a macroscopic clone of descendants comprising at least 50 'normal' (that is, non-giant) cells.

The loss of this capability is at present described in a variety of ways: 'cellular death', 'cellular lethality', 'reproductive death', or 'reproductive incapacity'²; 'inhibition of clone formation', 'damage to reproductive capacity', or 'inhibition of unlimited proliferation'³; 'lethal events' or 'killing'⁴; 'reproductive cell killing', 'loss of reproductive integrity' or 'cell killing'⁵; 'effect on ability to proliferate'⁶; 'loss of proliferative capacity'⁷; 'loss of proliferative integrity', or 'lethality'⁸.

May one now enter a plea for a return to the succinct terminology of Puck and Marcus? These authors pointed out the analogy between their technique with irradiated HeLa cells and those with irradiated bacteria. They also showed that the term 'cell killing' had long had a specific meaning in microbiology, referring only to the ability of an individual cell to produce a macroscopic colony. In the absence of full knowledge of the mechanisms involved in the prevention of clone formation by irradiation, it is difficult to describe the phenomenon without ambiguity. But the use of a standard phrase in all reports of radiobiological investigations involving single cell plating techniques would seem to be a step in the right direction; and 'cell killing' is proposed as being the most suitable choice.

BIOLOGY

Ultrastructure of the Antigen-retaining Reticulum of Lymph Node Follicles as shown by High-resolution Autoradiography

PREVIOUS investigations in this laboratory^{1–4} have described the localization of antigens in lymphoid follicles. Much circumstantial evidence was presented for the existence in follicles of a highly specialized fine dendritic web of macrophage fibrils responsible for antigen trapping and retention. Light microscopy alone, however, provided inadequate proof for the unequivocal demonstration of the structure of this web. The electron microscopic investigation reported here has defined more precisely the sites of localization of *Salmonella* flagellar antigen in the subpopliteal lymph node.

Whole flagella of *Salmonella adelaide* were labelled *in vitro* with iodine-125 by the direct oxidation method of Hunter and Greenwood as has been described elsewhere⁵. Ten-week-old normal Wistar rats were injected in one hind-foot pad with 20 µg flagella containing 1 mc. iodine-125 (0.7 g atom iodine-125 per 30,000 flagella). The draining popliteal lymph node was removed one to five days later, diced into pieces of about 2 mm³, fixed in cold buffered OsO₄ (ref. 6), dehydrated in ethanol and embedded in 'Araldite'. Throughout the fixation and dehydration, less than 5 per cent of the node's total radioactivity was lost⁷, despite the large area of exposed surfaces.

A section 2 µ thick, embracing the total available area of tissue, was cut from each block and mounted on a gelatine-coated slide for normal autoradiography with Kodak NTB-2 emulsion. To facilitate subsequent staining with methyl green-pyronin, the 'Araldite' was removed from the section with sodium methoxide⁸ before the emulsion was applied. Exposure for one day was sufficient to allow the detection of labelled follicles under 100-fold magnification. The position of a heavily labelled follicle was noted on the autoradiograph, the 'Araldite' block oriented appropriately and then trimmed to the size of the specified area comprising a follicle and some perifollicular tissue. Other blocks were prepared to contain typical areas of heavily labelled lymph node medulla. Ultra-thin sections displaying silver to pale gold coloration were cut with glass knives on a Huxley ultramicrotome and mounted on collodion coated slides⁹. Matching sections (0.5 µ) were cut to enable precise light microscopic autoradiographic correlation studies to be made.

The technique of high-resolution autoradiography developed by Salpeter and Bachmann⁹ with Kodak NTB-2 emulsion was used with the following modifications: (1) the slides were fire-polished¹⁰ before being coated with collodion; (2) sections were either unstained, or were stained for 0.5–2 h (before or after mounting) with 1 per cent aqueous uranyl acetate; (3) the emulsion was applied by dipping the slides into a Coplin jar containing diluted⁹ NTB-2 emulsion. After exposure for 1–3 months the slides were developed by passing them through the following solutions: 'Dektol' (Kodak, diluted 1/2) at 24° C, 1 min; 3 per cent CH₃COOH, 10 sec; water, 5 sec; 'Amfix' (May and Baker, Australia), 30 sec; water, 2 min. Finally, the slides were soaked in distilled water for 1 h or overnight before the collodion film was scored around the area of the sections and then stripped from the glass. Sections were mounted on either annular copper grids of 1-mm internal diameter¹¹ or NEW 100 'Athene' grid (Smethurst High-Light, Ltd., England). A Siemens UM100E4 electron microscope was used with a 50-µ objective aperture and was operated at 60 kV. Specimens were photographed at magnifications ranging from × 1,250 to × 7,200.

The specificity of the developed grains was established by locating the label on serial sections. With the development régime used, the grains appeared as round or

Fig. 1. Electron microscopic autoradiographs of a primary follicle from the popliteal lymph node of a rat injected with ^{125}I -labelled *Salmonella* flagella. A, Note the heavy label associated with fine cytoplasmic processes. L, Lymphocyte. ($\times c. 19,260$). B, Magnification $\times 11,300$. A lymphocyte surrounded by membrane-associated clumps of label.

comma-shaped dots (diam. $400 \pm 200 \text{ \AA}$), rather than as spirals. Significant background labelling was not seen, so that two or more grains at the one location could be identified with some confidence as specific label. By making a photo-montage of the complete section, the exact nature and location of labelled cells could be correlated with the more familiar and characteristic appearance of the matching autoradiograph in the light microscope.

The results showed that label in primary lymphoid follicles was indeed associated with fine cytoplasmic processes lying between the lymphoid cells (Fig. 1), thus confirming the previous findings and speculations⁴. The processes appeared to be long, fine, convoluted extensions of dendritic reticular cells. The label showed close association with the cytoplasmic membrane of these processes, a fact that was more readily apparent from inspection of areas where the density of grains was lower than in Fig. 1. The lack of label of the body of reticular cells and of the broader processes emanating from them (Fig. 1A) suggested that the antigen was preferentially located at the terminal arboreal regions of the dendritic processes.

The association between labelled dendritic processes and adjacent lymphocytes was extremely close (Fig. 1B). In some cases the contact was so intimate that it was impossible to determine whether label emanated from the process of a reticular cell or from the cytoplasmic membranes of the lymphocyte itself. The labelled dendritic processes were distinct from the cytoplasmic extensions which often ensheathed clumps of collagen fibrils. Furthermore, the dendrites did not appear to emanate from the 'tingible body' macrophages¹² which contained no obvious intracellular label.

The findings in the lymph node medulla were strikingly different. Here the label was located almost exclusively in the cytoplasm of typical macrophages (Fig. 2), much of it being associated with large granules and vacuoles. There was no evidence of label specifically associated with cytoplasmic processes or cell membranes.

Fig. 2. Portion of a medullary macrophage showing intracellular label predominantly associated with electron dense granules. N, Nucleus of the macrophage. ($\times c. 19,300$)

We conclude that there are two basic mechanisms for antigen retention in lymph nodes. In the lymphoid follicles there is a mechanism whereby antigen becomes

associated with the surface of dendritic processes of reticular cells, where it comes in contact with lymphocytes. By contrast, in the medullary sinuses antigen is retained intracellularly in the inclusions of typical phagocytic cells. The distribution of label in lymphoid follicles leads us to suggest that the term 'phagocytic reticulum' which we have previously used⁴ in relation to this area should be replaced by the term 'antigen-retaining reticulum'. It is tempting to speculate that the two patterns of lymph node antigen distribution reflect different facets of the immune processes.

We thank Prof. G. J. V. Nossal and Dr. G. L. Ada for their advice and Mr. J. Pye for performing the iodinations. This work was supported by grants from the National Institute of Allergy and Infectious Diseases, U.S. Public Health Service (AI-0-3958), to Prof. Nossal, and from the National Health and Medical Research Council, Australia. Some batches of iodine-125 were a gift of Glaxo Laboratories, England.

Zinc and Other Metallic Ions as Hatching Agents for the Beet Cyst Nematode, *Heterodera schachtii* Schm.

SOME inorganic salts stimulate eggs of the beet cyst nematode, *Heterodera schachtii* Schm., to hatch, but less effectively than diffusate from sugar-beet roots¹⁻³. The effective ions are potential oxidizing agents. We have extended hatching tests to some metallic ions not previously tried, including Ba²⁺, Al³⁺, Pb²⁺, MoO₄⁻, Mn²⁺, Co²⁺, Zn²⁺ and Cd²⁺, and have re-tested some salts (MgCl₂, KCl, NaCl, HgCl₂ and FeCl₃). Copper, previously tested as the sulphate, was tested as the chloride, and chlorides of the other metals were included in tests wherever possible. All salts were first tested at a concentration of ~3 mM in water and those with some activity were tested again over a range of concentrations. The hatch of eggs (Table 1) is expressed as a hatch rating³:

$$\frac{H_s - H_w}{H_d - H_w} \times 100$$

where H_s is the hatch in the substance, H_d is the hatch in beet root diffusate and H_w is the hatch in distilled water, and also as a percentage of the total number of eggs in the cysts.

Zinc sulphate, zinc nitrate and zinc and cadmium chlorides proved potent hatching agents; twelve other salts were moderately or weakly active, and ten were inactive or inhibitory. The zinc salts and cadmium chloride are more effective than the other inorganic hatching agents for *H. schachtii*³ although neither anion nor cation is a potential oxidizing agent. The activity of these two chlorides (zinc and cadmium) was not caused by hydrochloric acid formed by hydrolysis, because hydrochloric acid itself is only moderately active at its optimum concentration.

Table 1. THE ABILITY OF VARIOUS METALLIC SALTS TO STIMULATE HATCHING OF *H. schachtii* EGGS EXPRESSED AS A HATCH RATING AND ALSO AS A PERCENTAGE OF THE TOTAL NUMBER OF EGGS IN THE CYSTS

Based on total hatch after three weeks from three batches of 100 cysts

Compound	Concentration (mM)	Hatch rating	Percentage hatch
Zinc chloride	4*	180†	64
Cadmium chloride	0.6*	177	56
Zinc sulphate	2	127	55
Zinc nitrate	2	113	45

Sodium nitrate	6	-88	1
Mercuric chloride	0.6*	-95	1

* Optimum concentration in a dilution series.

† Bold type indicates hatch as good as or better than in root diffusate which is 100 ± 10.

‡ Negative sign indicates percentage inhibition compared with the hatch in water, which is 0 ± 10.

Because of its potency in causing *H. schachtii* eggs to hatch, we tested the ability of zinc chloride to hatch eggs of other *Heterodera* species: *H. avenae*, *H. carotae*, *H. cruciferae*, *H. glycines*, *H. goettingiana*, *H. rostochiensis*, *H. tabacum* and *H. trifolii*. With *H. avenae*, where the number of eggs which hatch in oat-root diffusate and in water is the same, zinc chloride inhibited hatching slightly. With *H. goettingiana*, where only very few eggs hatch either in water or in pea-root diffusate *in vitro*, a few more larvae hatched out in zinc chloride. With all the other species, zinc chloride caused more eggs to hatch than did water, and with most of these species hatching was as great as or greater than that in the root diffusate from their host plants. As with other agents that stimulate hatching, it is not known how Zn²⁺ and Cd²⁺ ions act.

Failure of the Zona Reaction in Five Pig Eggs

In most mammals which have been examined, the first spermatozoon that penetrates into the egg stimulates the egg to undergo a reaction which prevents subsequent spermatozoa from traversing the zona pellucida¹. This phenomenon is called the 'zona reaction'. In the pig following the zona reaction, spermatozoa can still penetrate into the zona but they normally cannot traverse it². However, eggs aged for several hours before exposure to the first spermatozoon sometimes fail to elicit the zona reaction and several spermatozoa enter the vitellus (polyspermy) to become male pronuclei (polyandry)³.

In the course of examining several hundred recently fertilized pig eggs, we observed five eggs which did not exhibit a zona reaction. The first of these came from a litter of nine eggs recovered about 8 h after ovulation. Eight of these were at normal stages while one egg (egg A) was unusual in that it contained two spermatozoa in the perivitelline space (Fig. 1). After the egg was fixed in acetic-alcohol and stained with orcein, a vesicular nucleus was revealed (Fig. 2). Hancock⁴ reported that out of 1,677 pig eggs examined, three had vesicular nuclei. The second egg that had not undergone a zona reaction came from a litter of five eggs recovered 54 h after insemination

four of these were normal, fertilized, four-celled eggs while the fifth (egg B) was one-celled and contained more than twenty spermatozoa in the perivitelline space (Fig. 3). Unfortunately, egg B was lost during fixation so that its nuclear status could not be determined. Eggs D, and E (Figs. 4, 5, and 6) were recovered 10–16 h after ovulation and were found to contain 10–15 accessory sperm in the perivitelline space and to have vesicular nuclei. We are not aware of any other recorded observation describing spermatozoa in the perivitelline space of a pig egg.

Pig eggs, and most other mammalian eggs examined, are normally in second metaphase at the time of ovulation. Polge and Dziuk⁵ found twenty-eight eggs with vesicular nuclei during a study of 1,472 recently fertilized pig eggs, and nine of these twenty-eight each had a spermatozoon in the cytoplasm but pronuclei had not formed, such as is shown in Fig. 6. Some eggs, therefore, fail either to receive or to respond to the signal for initiation of meiotic development and maturation prior to ovulation. Eggs A, C, D and E had vesicular nuclei and therefore were not fully mature. This suggests that as an egg matures meiotically it concomitantly develops its ability to elicit a zona reaction. This hypothesis could be tested by transferring follicular

eggs at various stages of maturation into the oviduct of recently mated sows. After an appropriate time-interval these eggs would be recovered and examined to see whether spermatozoa are present in the perivitelline space.

Effects of (2-Chloroethyl)trimethylammonium Chloride and Gibberellic Acid on Growth, Fruit Bud Formation and Frost Resistance in One-year-old Pear Trees

THE growth retardant *N*-dimethylaminosuccinamic acid (B-995) has been shown to modify growth in various fruit trees^{1–3}.

In experiments at East Malling, another growth retardant, (2-chloroethyl)trimethylammonium chloride (CCC), has shown similar effects on pear trees. A single spray with 1 per cent CCC, applied on May 25, 1964, to 1-year-old pear trees of the variety 'Williams' Bon Chrétien', halved the total new shoot-length and greatly increased the number of fruit buds. These effects were obtained regardless of any pre-treatment of the trees with gibberellic acid (GA).

Four sets of ten trees were sprayed with GA at 500 p.p.m. on the following dates: (A), April 18, April 29 and May 4, 1964; (B), April 29 and May 4; (C), April 29 only; (D), April 18 only. A fifth set (E) was left unsprayed. On May 25, half the trees in each set were sprayed with 1 per cent CCC (treatment F).

The results are shown in Figs. 1–3. The GA sprays had no effect on primary shoot growth, but the triple GA spray (treatment A) increased both secondary and axillary shoot growth. The single CCC spray dramatically reduced shoot growth, regardless of whether or not GA had previously been applied (Fig. 1). Fruit bud formation was reduced by triple GA spray, but greatly increased by the CCC spray in every case (Fig. 2). Fig. 3 shows the appearance of trees of the most contrasting treatments E, EF, and A in the following spring.

On April 26, 1965, when the trees were in full bloom two trees of each treatment were exposed to a freezing cycle,

Fig. 1. Egg A with spermatozoa in perivitelline space (arrows) (fresh whole-mount; $\times c. 225$)

Fig. 2. Egg A showing vesicular nucleus (arrow) (fixed and stained; $\times c. 125$)

Fig. 3. Egg B showing several spermatozoa in perivitelline space (arrows) (fresh whole-mount, $\times c. 280$)

Figs. 4 and 5. Eggs C and D showing spermatozoa in perivitelline space (arrows) (fresh whole-mounts, $\times c. 280$)

Anatomical Changes associated with Juvenile-to-Mature Growth Phase Transition in *Hedera*

THE morphological change which accompanies a juvenile to-mature transition in various plant species has received considerable attention in recent years¹⁻⁷. Some workers have attempted to relate biochemical^{8,9} and anatomical factors to those changes which are so striking in certain plants as to give the impression that the mature phase is an entirely different species. These studies confirm the findings of Beakbane¹¹ and extend her hypothesis concerning adventitious rooting.

Leaf, stem, root, and vegetative bud tissue was taken from actively growing juvenile, transitional, and mature phase plants of ivy (*Hedera helix*) and prepared for microscopic examination. In addition, flower buds of mature plants were studied. Stem sections were taken 2 cm below the apex. All tissues were prepared by dehydration in the tertiary butyl alcohol series, embedding in paraffin, staining with safranin-fast green, and sectioning with rotary microtome at 10μ .

Tissues were examined for characters which might be associated with a change in growth phase. No gross anatomical differences were noted in the leaves, roots, or buds of juvenile and mature tissues. However, one striking difference was observed in the cross-section of the stem. In addition to the anticipated greater lignification of tissues in the mature stem, a discontinuous ring of fibres encircled the phloem in these plants (Fig. 1, top). Phloem fibres were extremely rare in juvenile stems (Fig. 1, bottom). Transitional stems, beginning to show some mature morphology, possessed a few fibres which became more numerous as the maturing plant progressed in age.

Previous reports of difficulty in the vegetative propagation of mature *Hedera*^{9,12} resemble those reported by Beakbane¹¹ in various woody plants. She has shown that shoots of difficult-to-root plants often have a high degree of differentiation into fibres and sclereids. In 'Conference' pear an almost continuous ring of thick-walled fibres encircled the phloem. She found an inverse relationship between ease of rooting and continuity of the ring. Stoutemyer¹⁰ found that the mature phase stem in apple contained more pericyclic fibres than the juvenile form. Differences in response of cuttings from non-flowering and flowering plants have been correlated with differences in anatomical structure, the flowering stem containing a higher proportion of xylem¹³. Flowering of seedlings was also found to be associated with the structure of the stem. Struckmeyer¹⁴ showed that the cell walls of stems of various flowering plants had become greatly thickened, and changes in anatomical structure occurred early in the development of plants placed in an environment favourable to the formation of flower primordia.

This experiment supports Beakbane's suggestion that an increased difficulty in rooting is associated with increased fibre development in mature stems. Also supporting Beakbane, it is difficult to conceive that such a correlation could explain the rooting problem strictly on the basis of a mechanical barrier, since in no case observed in *Hedera* was the fibre ring continuous so as to form a lignified cylinder. Beakbane also refers to difficult-to-root plants, such as *Pittosporum*, in which no sclerenchyma is present. Recent experiments by Sachs, Loreti, and De Bie¹⁵ showed no simple relationship between density and

VIROLOGY

Milker's Nodule Virus Infections in Dorset and their Similarity to Orf

BETWEEN January 1964 and March 1965 seven farm workers on six Dorset farms developed lesions on the hand or forearm which were diagnosed as clinically typical orf infections. Material from each patient was examined by electron microscopy and tissue culture as previously described^{1,2}. In each instance pox-virus particles were seen which in morphology and size were identical with orf virus³. In tissue culture four specimens produced the same cytopathic changes as orf virus and serial passage of three virus strains was obtained in primary human amnion and rhesus monkey kidney. No difference in behaviour was noted between these strains and orf virus strains previously grown from humans infected from sheep.

Orf virus infection of sheep is well known as contagious pustular dermatitis (CPD). None of our seven patients had been in contact with sheep, but all had milked cows within three weeks of onset of their lesions. Orf infection of cattle has not been reported, so these human infections would have been diagnosed as milker's nodules or pseudocowpox if the animal source of infection had been considered of prime importance⁴⁻⁷.

Investigation of the six dairy herds revealed teat lesions on some animals in all six herds. Two distinct types of lesion are recognizable: (1) *Benign or chronic*. This is a mild erythema of the teat which is quickly followed by profuse scabbing. The scabs are soft, scurfy and yellowish-grey and are often rubbed off at milking. The teat surface becomes corrugated and prone to develop chaps and sores. The lesions are painless throughout their course and persist for several months. This type of lesion seldom affects many cows in a herd. (2) *Acute*. An erythematous eruption of the teat develops into a small vesicle or pustule which ruptures within 48 h. Prolific scab formation follows rapidly, some of the scabs being very large. Pain is only noticeable before scab formation, and indeed, scabs can be removed with no response by the cow. Granulation develops beneath the scab until the lesion becomes elevated some 2-3 mm above the general teat surface, and varies in diameter from 0.5 to 2.5 cm. The lesions heal from the centre, and, when the scab drops or is rubbed off, a characteristic horseshoe-shaped ring of minute scabs at the circumference is left. Each lesion takes 7-10 days to this stage. A small wart-like granuloma then remains, marked out in the early days by the horseshoe ring, and persists for many months, several of these making the teat very coarse. Spread of the lesions from cow to cow appears to be slow, and 5-10 per cent of the herd is usually affected at any one time. Freshly calving animals and those recently entering the herd are most often affected. Two herds had an epidemic of the infection which appeared a few weeks after their arrival from a different county.

Scabs were collected when present and small biopsies were made of the other types of lesion. As shown in Table 1, identical pox-virus particles were found in the

Fig. 1. Cross-sections of mature (upper) and juvenile (lower) stem of *Hedera helix*. Arrow points to fibres peripheral to the phloem in the mature stem.

continuity of sclerenchyma and ease of rooting in seven varieties of olive cuttings. Indeed, if the correlation described by Beakbane, and supported by the present work, is significant, a chemical involvement must be assumed.

One other point deserves mention concerning *Hedera* morphology and anatomy. As the ivy proceeds from the juvenile to mature growth phase, changes in leaf shape, stem shape, anthocyanin content, formation of aerial roots, and phyllotaxy occur. In addition, growth habit changes from a distinct plagiotropic to an orthotropic form. Probably the strengthening of stems, and change to a shrubby habit, may be associated with the increased shoot lignification and development of fibres. The additional shoot strength imparted by the fibres is apparently sufficient to change *Hedera* from a vining to an upright growth habit.

6	A.H.	"	N.D.	-	6	4	N.D.	N.D.

Passages given are number attempted. The virus from M.J.P. produced typical cytopathic changes but failed to passage. The others showed no evidence of decreasing infectivity when passage was discontinued.

N.D., not done.

five herds from which specimens were obtained and growth in tissue culture was successful. The virus behaved in every way like the human strains. Orf infection of lambs and ewes is enzootic in Dorset, the virus having been isolated by us both from sheep and from shepherds. The possibility of transfer of orf infection from sheep to cattle was considered, but no evidence of such transfer was found. In order to find out how common teat lesions might be among dairy herds in West Dorset which were not associated with human infections, 16 herds were inspected. Teat lesions were found in some animals in every herd. At least four presumptive human infections were also found although too late for laboratory investigation. Confirmation of the bovine infections was possible in 14 of the 16 herds. As only one specimen was examined from each of the two negative herds, this does not exclude their infection. Of 48 animals examined, 36 had the pox-virus infection, 5 bovine warts and 7 animals were negative. The infection is therefore enzootic. No marked seasonal variation was evident. Lesions of the mouth in calves have not been seen, but few calves were suckled for more than three days because these were dairy herds.

It has been found that electron microscopy is a quicker and more reliable method than tissue culture for examination of this kind of material. Bacterial and fungal contamination of the specimen is heavy and the virus grows slowly. When only small numbers of virus particles are present successful culture is far less likely, as shown in Table 2. No positive results were obtained with cultures when microscopy was negative. Microscopy is therefore an invaluable tool for this type of field investigation and could be applied on a large scale provided that adequate cultural confirmation is included.

Comparison of the growth of cattle and sheep virus strains in a variety of tissue culture cells is shown in Table 3. No consistent differences were observed in the range of cells affected, in the type of cytopathic change, or in the number of successful passages possible. Both viruses have a tendency to die out and the differences shown appear to be no greater than between different strains of either source. Growth in primary cells is more reliable and yields more virus than in continuous cell lines. Most strains have passed 10 or more times in primary cells without dying out.

There are several aspects of the work presented that seem worth consideration.

Table 2. COMPARISON OF NUMBER OF BOVINE POXVIRUS PARTICLES SEEN BY MICROSCOPY WITH CULTURAL RESULT

Virus particles per grid square*	Tissue culture	
	Positive	Negative
1,000-	1	0
100-1,000	10	0
10-100	8	6
1-10	6	4
0	0	12

* A standard 2.30 mm electron microscope grid has squares of approximately $100\mu \times 100\mu$.

(1) *Human lesions.* Infection with this bovine virus and ovine orf can produce a variety of clinical lesions man from multiple vesicles to the classical single indurated nodule. When the animal source is unknown, or doubt, it is not possible in our experience to differentiate between ovine and bovine infections. A wider experience might enable this, but all the dermatologists we have consulted so far have agreed that differential diagnosis is based on knowledge of the animal source. The shepherds are said to have orf whereas a similar lesion on a cowman is called a milker's nodule. We feel that thorough comparison of the lesions is likely to show the same pathology irrespective of the source of infection.

(2) *Bovine lesions.* This infection of dairy cattle hitherto unsuspected, is clearly enzootic in Dorset. The it came to our notice by the appearance of the human infections is suggestive of a higher recent incidence perhaps due to changes in farming, as three infections were from two herds with epizootic infection in consequence of being recently moved into the county.

There is no information at present on the incidence of infection elsewhere in Britain, but it is probably widespread and might be the 'spurious cowpox' described by Jenner in 1799 (ref. 6).

Teat lesions in dairy cattle tend to be regarded as due to minor trauma, chapping in cold weather, etc. But it is worth consideration that even trivial lesions are prone to secondary bacterial infection and this is one way in which bacterial infection of a teat could occur which might lead to mastitis.

(3) *The relations of the bovine virus.* The poxvirus are divisible into two groups by morphology. The large group have the vaccinia type of structure, the smaller one that described for orf^{3,8}. We refer to the latter as the orf group because of the antiquity of the word 'orf' that is Old English *hreo*: rough, scabby⁹, and orf-quail cattle plague¹⁰, and the fact that this morphological type was first described by Abdussalam and Cosslett in 1957 (ref. 8) for ovine virus, in preference to the suggested use of 'paravaccinia' group recently proposed by Peters *et al.*¹¹.

So far the orf structural group includes the viruses of orf or contagious pustular dermatitis^{3,8,12}, milker's nodule or pseudocowpox virus^{6,7}, bovine papular stomatitis virus^{13,14}, chamois contagious ecthyma^{15,16} and that described recently by Pournaki *et al.* as bovine X or BX virus¹⁷. We consider that our bovine virus is synonymous with those described as milker's nodule, pseudocowpox and BX. Its relationship to bovine papular stomatitis (BPS) virus remains to be determined. Plowright and Ferris¹⁸ consider BPS to be synonymous with the proliferative stomatitis described in the United States by Olson and Palionis¹⁹ and several other stomatitis agents. It is noteworthy that two of the American workers developed milker's nodes on their hands, and material from these injected into calves produced stoma-

itis. BPS strains are not readily available in Britain and we have been unable to find evidence of natural infections.

The relationship of the bovine strains to orf and the other animal viruses will remain conjectural until further work, especially serology, is complete, but on present evidence their similarity appears so close as to make separation difficult.

We thank Mr. G. H. C. Ellis, Mr. W. MacKinnon, Mr. J. Hall and Mr. M. H. Woodford for their help, and Prof. J. D. Boyd for enabling us to use the electron microscopy facilities of the Department of Anatomy, Cambridge.

Plant Tumour Virus in Arthropod Host: Microcrystal Formation

THE wound tumour virus (WTV) belongs to a group of plant pathogenic viruses that infect not only plants but also their respective arthropod carriers¹. The virus has been detected in extracts of an insect vector and found to multiply in this vector, the clover leafhopper *Agallia constricta* van Duzee². Purified preparations of WTV from plant and insect hosts permitted the determination of the particle size and its morphology³. Purified WTV particles, about 600 Å in diameter, have the shape of an icosahedron with a surface of 92 sub-units, about 75 Å in diameter⁴. The virus core stains heavily with uranyl acetate and comprises about 20 per cent of the volume of the particles. It consists of a double-stranded RNA⁵. The virus reaches considerable concentrations in extracts from insects and plant tumours, but the infection of the insect host is not apparent⁶.

Until we undertook this investigation, it was not known whether WTV particles could be visualized in tissues of an insect vector *in situ*. The presence, in the cell cytoplasm of both healthy and virus-infected insects, of numerous spherical particles makes it extremely difficult to differentiate between normal cell constituents and virus, unless special circumstances arise which make identification possible.

Clover leafhoppers, *A. constricta*, were confined for 4 weeks to sweet clover (*Melilotus officinalis* L.) plants infected with WTV. Afterward, whole abdomens were dissected and fixed for 90 min in a 6 per cent glutaraldehyde and insect Ringer solution. This was followed by washing with 3 changes of distilled water for 30 min each, and further fixation in 2 per cent osmium tetroxide

for 60 min. After dehydration in graded ethanol, the pieces were embedded in methacrylate or epoxy resin. Ultrathin sections were cut with a Porter-Blum MT-1 microtome, using a diamond knife for epoxy, and a glass knife for methacrylate resin. The sections, approximately 25–50 mμ thick, were double-stained (for epoxy embedded materials) with 6 per cent uranyl acetate for 60 min and with lead for 15 min⁷. Electron micrographs were taken with a Siemens Elmiskop I, with 80 kV accelerating voltage.

Although the size and shape of WTV were known from purified preparations, the identification of isolated particles would have presented a difficult task. Fortunately, striking accumulations of particles, forming crystalline arrays, were encountered in the cytoplasm of muscle and fat body cells. Since these particles, found in crystalline arrangement, resembled in size and shape WTV particles, and since such particles were never observed in non-infected insects, it was concluded that the regular accumulations were WTV microcrystals. This conclusion was further confirmed by the finding of particles of the same size and morphology in WTV-infected plants, particularly in root and stem tumours of diseased sweet clover plants, and in WTV enations of *Rumex acetosa* and enlarged veins of WTV-infected *Trifolium incarnatum*⁸, but not in healthy plants of the same species. Similar regular arrangements and distances between particles of the same size as found in the microcrystals were observed by Whitecomb (unpublished results) in a cross-section of a pellet of purified WTV.

Fig. 1 shows one of the striking accumulations of WTV microcrystals in a single fat body cell of *A. constricta*. Individual microcrystals of compactly packed WTV particles were also encountered within microfibrils of muscle fibres, as shown in Figs. 2 and 3. These electron micrographs of microcrystalline virus inclusions indicate the regular, three-dimensional arrangement of the particles. When the microcrystals were found in fat body and muscle cells, it was not known whether they also occur in other organs of the arthropod host. The time-consuming part of our work was the subsequent identification of particles, particularly of individual ones or of very small WTV accumulations⁹. The finding of virus microcrystals, on the other hand, turned out to be easier than was anticipated. It should be pointed out that the size of the WTV inclusions is smaller than, or similar to, mitochondria, which makes their structural identification difficult under a light microscope.

The diameter of the virus particles within a microcrystal was calculated as 58–60 mμ. These measurements were made on epoxy embedded materials, including central darker areas surrounded by less dense regions.

Fig. 1. Crystalline inclusions (microcrystals) of wound tumour virus (WTV) in the cytoplasm of a fat body cell of *A. constricta*.

Parsons⁹ summarized the differences in size between isolated virus particles and those obtained from ultrathin sections of animal viruses. It was known that methacrylate polymerization causes considerable shrinkage and distortion¹⁰. Therefore, the diameter of virus particles in methacrylate-embedded sections was expected to be smaller than the diameter of purified WTV particles. This was confirmed in the results shown in the legends to Figs. 2, 3 and 4. Centre-to-centre measurements resulted in different average diameters, when the measurements were made from different directions.

Electron micrographs of some WTV microcrystals clearly showed the regularly repeated pattern of darker and lighter particles (Fig. 4), corresponding with the denser and less dense masses of regularly arranged units. Obviously, in such sections, the cutting face of the knife was not parallel to the surface of the WTV microcrystal. The darker particles have a central core, while the less dark ones are devoid of the core.

The nature of the crystal formation is not clear. It is feasible to assume that they represent the result of virus multiplication at the site where they are found. In the

Fig. 2. Cross-section through a WTV microcrystal within microfilaments of a muscle cell of *A. constricta*. Epoxy resin embedding. Average diameters of 42 particles were: first direction (8 particles): 66.8 mμ; second direction (6 particles): 66.0 mμ; third direction (8 particles): 57.5 mμ; fourth direction (6 particles): 57.6 mμ; fifth direction (8 particles): 61.7 mμ; sixth direction (6 particles): 61.9 mμ. Single particles inside crystal (3 particles): 59.4 mμ single particle, outside microcrystal: 57.8 mμ

Fig. 3. Cross-section through a WTV microcrystal in *A. constricta* muscle cell. Epoxy resin embedding. Average diameters of 9 particles were: first direction—70.5 mμ; second direction—72.5 mμ; third direction—69.5 mμ. Single particle inside microcrystal measured 63.0 mμ × 59.6 mμ

Fig. 4. Cross-section of a WTV microcrystal, embedded in methacrylate resin. Average diameters of 20 particles were: first direction—45 mμ; second direction—35 mμ. Average diameters of 10 particles in a loose cluster within same fat body cell were 57 mμ and 38 mμ for the two directions

case of animal viruses in animal host cells, such a hypothesis had been put forward by several workers^{11,12}. However, some virus particles are not arranged regularly in the cytoplasm¹³. While it appears likely that virus multiplication occurred in the cytoplasm of the cells in which the microcrystals were encountered, these regular arrangements of particles could also represent the final stage of storage and accumulation of particles that have multiplied earlier in a viroplasmic matrix situated at another part of the cell.

The novel and unusual feature of the present findings is the formation of microcrystals of a plant-pathogenic virus in an animal host. So far as the authors are aware, this is the first such account. Regular arrangements of rice dwarf virus have also been reported in an insect vector¹², but electron micrographs of that virus did not suggest the formation of a crystalline three-dimensional structure. It should be pointed out that WTV microcrystals were also found in some cells of infected plants, alongside of large accumulations of virus particles and irregularly scattered WTV⁷.

VETERINARY SCIENCE

Development of *Eimeria tenella* in Avian Embryos

MORE than 300 species of the genus *Eimeria* have been recorded from birds and mammals¹. Where details of the life-cycles are known, only two species appear to develop in sites other than the intestinal tract. These species, *E. stiedae* and *E. truncata*, occur in the liver of the rabbit and the kidney of the goose respectively and are not known to develop at other sites. Infection of hosts normally occurs after the introduction of sporulated oocysts by mouth and the development of species, other than *E. stiedae* and *E. truncata*, is confined to the intestine. *E. tenella* usually shows a rigid preference for the caecal mucosa of the domestic fowl although, in common with the other species of *Eimeria* in the fowl, the sporozoites are released in the small intestine. When this parasite is introduced by either the intravenous or intraperitoneal routes developing stages can only be located in the caeca²⁻⁴.

This rigid site selection does not necessarily apply to *E. necatrix* or *E. brunetti* as sporozoites introduced directly into the caeca invade the walls and complete their life-cycles in the usual way^{5,6}. The present investigation shows that *E. tenella* can develop in the chorioallantoic membrane of the chick embryo.

Sporozoites were released from the oocysts by using a modification of an *in vitro* excystation method⁷. In pre-

liminary experiments, sporozoites injected into the allantoic cavity or intravenously caused the early deaths of ten-day-old embryos. Deaths usually occurred immediately after the intravenous injection of sporozoites whereas deaths occurred up to 24 h after allantoic injection and were associated with heavy bacterial contamination. To control contamination, the oocyst suspensions were incubated at 30° C for 24 h in peptone broth containing 50 i.u. penicillin and streptomycin per ml. This procedure was followed by a 1 h treatment in 1:500 'Chlorox' solution and finally in 2 per cent formalin solution. The oocysts were washed in sterile 0.9 per cent sodium chloride between each treatment and then excysted. The findings following the inoculation of sporozoites are summarized in Table 1.

Sporozoites injected into the allantoic cavities of ten-day-old embryos produced infections and fewer early deaths than in six-day-old embryos. Intravenous inoculation of sporozoites produced no developing stages. Intramniotic inoculation was highly lethal and sudden deaths occurred associated with multiple haemorrhages.

In the infections which occurred from injections of sporozoites into the allantoic cavity parasites were only detected in the chorioallantoic membranes and not in the embryo itself. Immature and mature schizonts were seen in increasing numbers in histological sections of the chorioallantoic membranes on days 4, 5, 6 and 7 and numerous merozoites were found in the allantoic fluid on days 6 and 7. Schizonts, morphologically similar to those found previously, were also readily seen on days 8 and 9.

Table 1. THE EFFECT OF INTRODUCING SPOROZOITES OF *E. tenella* INTO AVIAN EMBRYOS BY DIFFERENT ROUTES

Number of sporozoites inoculated (10 ³)	Volume inoculated (ml.)	Site of injection	Age of embryos	Number injected	Early deaths		Findings
					No.	Time	
140	0.1	Intravenous	11	6	5	Within 72 h	One survivor, killed day 7, no parasites
140	0.1	Allantois	11	6	3	Within 72 h	In 2 survivors schizonts and oocysts present in C.A.M.* on days 5 and 10 after infection. One survivor negative on day 10
24-38	0.05-0.08	Intravenous	5	9	2	2-24 h	All negative for parasites when examined between 5 and 11 days after inoculation
48-240	0.1-0.5	Amnion	10	8	8	Within 24 h	Multiple haemorrhages
108	0.1	Allantois	6	12	7	Within 48 h	In 3 survivors schizonts were found in the C.A.M. on days 4, 5 and 7 after inoculation. No parasites were found in embryos examined on days 8 and 9 after inoculation
64	0.05	Allantois	10	20	1	Within 24 h	The C.A.M.'s of all embryos were positive for parasites when examined between days 4 and 11 of infection. Schizonts were found from days 4-10, gametocytes and oocysts from days 7-11. Nine deaths occurred on day 7; numerous schizonts were seen in the C.A.M. and numerous free merozoites were seen in the allantoic fluid

* Chorioallantoic membrane.

(a)

(b)

Fig. 1. Mature schizonts in chorioallantoic membranes; sections stained by haematoxylin and eosin ($\times 600$). (a) Schizont from 14-day-old embryo 4 days after inoculation; (b) schizonts from 16-day-old embryo 6 days after inoculation

(a)

(b)

Fig. 2. (a) Gametocytes (g) in epithelial cells of the chorioallantoic membrane and oocysts (o) free in the allantois of a 20-day-old embryo, 10 days after inoculation with sporozoites. Stained by haematoxylin and eosin ($\times 210$). (b) Oocysts (o), gametocytes (g) and merozoites (m) in the same embryo. Unstained preparation ($\times 600$).

These schizonts were similar to the second generation schizonts of *E. tenella* in the caeca of hatched chickens on days 5 and 6 after receiving sporulated oocysts *per os*. The nine embryos found dead on day 7 after inoculation were presumed to be due to the very large numbers of schizonts in the chorioallantoic membrane and haemorrhage which occurred in the allantoic cavities. Gametocytes and oocysts were found in small numbers on day 7 and were found in increasing numbers until day 11. Oocysts were found free in the allantoic fluid and in necrotic material sloughed off from the chorioallantoic membranes. Photomicrographs of the different stages observed are shown in Figs. 1 and 2. The oocysts recovered from a ten-day-old infection sporulated normally and produced typical caecal infections when inoculated into one-week-old chickens.

The results show that the life-cycle of *Eimeria tenella* can occur at a site other than the caeca of the chicken and this may have important consequences. The life-cycle appears to be slightly delayed (large numbers of oocysts occurring after day 9 of the infection) and the phase of schizogony extended.

Maintenance of the avian *Eimeria* normally necessitates frequent passaging in fowls kept in strict isolation. The growth of *E. tenella* in the chick embryo may provide a more convenient and less expensive alternative. It is possible that other species of *Eimeria* also develop in embryos. An extension of this work is proceeding with other species of *Eimeria* of the fowl and *E. stiedae* of the rabbit. The method may be of use in the evaluation of anti-parasitic substances and, in addition, provides bacteria-free material for immunological investigations. Of particular interest is the apparent prolongation of schizogony of the parasite and the opportunity now afforded for studying the parasite in a host in which resistance is minimal⁶.

MISCELLANEOUS

Effect of Certain Types of Paper on Sexual Maturation of the Insect *Pyrrhocoris apterus*

ON reading the article entitled "Juvenile Hormone Activity for the Bug, *Pyrrhocoris apterus*", by Sláma and Williams¹, I was struck by a likely correlation.

These authors report that this European insect fails to undergo normal sexual maturation in the presence of certain American papers (*New York Times*, *Wall Street Journal*, *Boston Globe*, *Science* and *Scientific American*), while British papers (*The Times* and *Nature*) had no inhibitory effect on the attainment of normal sexual maturity by this insect.

The active principle in the paper was found to be heat stable (100° C) and insoluble in water, but soluble in methanol, acetone, ether and petroleum ether. The authors ascertained that balsam fir, hemlock and yew contained the active principle, while red spruce, European larch and southern pine possessed very little activity.

The heart wood of Douglas fir contains dihydroquercetin as was first shown by Pew², and this is well known in the American wood pulping industry, for this substance interferes with pulping and tends to oxidize to quercetin, which is yellow on account of its cinnamoyl resonance; this spoils the appearance of the paper, so steps are taken to prevent its oxidation.

Moewus³ showed that quercetin occupies a central position in the development of sexuality in the primitive biflagellate alga *Chlamydomonas eugametos*, being a precursor of isorhamnetin required in the female gametes and of peonin required in the males.

It might therefore be profitable for entomologists to ascertain whether the inhibitory substance may not be dihydroquercetin, which could well interfere with sexual maturation if quercetin should be a step in the pathway to sexual maturity in these insects, as it is in *Chlamydomonas eugametos*.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 1

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 9.30 a.m. and 2.15 p.m.—Colloquium on "HS 803 (Early Bird) and the Post Office Earth Station at Goonhilly".

PLASTICS INSTITUTE, PLASTICS PROPERTIES DISCUSSION CIRCLE (at the Mandeville Hotel, Mandeville Place, London, W.1), at 3 p.m.—Mr. D. R. Reid. "Ageing".

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. D. A. Price Evans: "Genetics and Drug Idiosyncrasy".*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. Ralph Audy (U.S.A.): "Red Mites and Typhus. I. Scrub-itch and the Ecologist".*

UNIVERSITY OF LONDON (in the Chemistry Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. D. J. Millen: "Molecular Measurements" (Inaugural Lecture).*

INSTITUTION OF MECHANICAL ENGINEERS, MEDICAL ENGINEERING WORKING PARTY (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Informal Discussion on "The Doctor's View of Engineering: The Engineer's View of Medicine".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"The Island" (film with introduction by Prof. C. A. Fisher).

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dame Kathleen Lonsdale, D.B.E., F.R.S.: "Crystallography as a Research Tool in Chemistry" (Jubilee Memorial Lecture).

Tuesday, November 2

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 1.30 p.m.—Mr. E. F. Schumacher: "Guides to Action: Is There a Universal Teaching of Mankind?"*

UNIVERSITY OF LONDON (at the Institute of Obstetrics and Gynaecology, Hammersmith Hospital, London, W.12), at 3 p.m.—Prof. P. Polani: "Human Chromosomes and their Abnormalities (II)".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. J. A. Banks: Presidential Address.

ROYAL INSTITUTION, LIBRARY CIRCLE (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Dr. H. D. Anthony: "The Study of Scenery".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. B. Kimmith: "Angiology of the Human Lymph System". (Fourth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation).*

UNIVERSITY OF LONDON (in the Large Physics Lecture Theatre, Westfield College, Kidderpore Avenue, London, N.W.3), at 5.30 p.m.—Dr. J. Sicher (Czechoslovak Academy of Science): "The Steric Structure of Medium Ring Compounds and Approaches to Conformational Analysis".*

UNIVERSITY OF LONDON (at Queen Mary College, Mile End Road, London, E.1), at 6 p.m.—Prof. W. R. Sears (University of Cornell): "Fundamental Ideas". (First of four lectures on "Magneto-Fluid Dynamics").*

PLASTICS INSTITUTE, LONDON SECTION (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Mr. H. Birtles: "The Government Services for Exporters".

Tuesday, November 2—Wednesday, November 3

INSTITUTION OF MECHANICAL ENGINEERS, HYDRAULIC PLANT AND MACHINERY GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1)—Symposium on "Surges in Pipelines".

PLASTICS INSTITUTE (at the Connaught Rooms, Great Queen Street, London, W.C.2)—Conference on "Automatic Control for Plastics Processing".

Wednesday, November 3

BIOMETRIC SOCIETY—BRITISH REGION (at the Wellcome Building, Euston Road, London, N.W.1), at 2.30 p.m.—Symposium on "Non-Parametric Methods". Principal Speakers: Mr. F. Sprent, Prof. F. Armitage, Mr. I. D. Hill and Dr. G. B. Wetherill.

COLOUR GROUP (Great Britain) (in the Physics Department, Imperial College, Prince Consort Road, London, S.W.7), at 3 p.m.—Mr. A. C. Hardy: "The Colour Coordination of Tiles and other Factory Coloured Products for the Building Industry in relation to BS 2660"; Mr. F. Malkin: "An Experiment in the Colour Tolerance of Glazed Wall Tiles".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. P. A. Bradley and Mr. C. Clarke: "Atmospheric Radio Noise and Signals Received on Directional Aerials at High Frequencies"; Mr. C. Clarke, Mr. P. A. Bradley and Mr. D. E. Mortimer: "Characteristics in Atmospheric Radio Noise Observed at Singapore".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Distribution and Application of Electricity in Building Sites".

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5.30 p.m.—Mr. M. H. Freeman: "Long Range Weather Forecasting".

ROYAL MICROSCOPICAL SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. R. W. Horne: "Electron Microscopy on the Macromolecular Level".

SOCIETY OF NON-DESTRUCTIVE EXAMINATION (in the Weir Lecture Hall, Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, W.1), at 5.30 p.m.—Mr. B. E. Byrne: "The Selection, Training and Briefing of N.D.T. Personnel" (Third Croxson Memorial Lecture).

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. Ralph Audy (U.S.A.): "Red Mites and Typhus. II. Akamushi: The Red Mites of Japan".*

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, ELECTRO-ACOUSTICS GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Dr. B. L. Clarkson: "High Intensity Acoustic Noise Sources".

Thursday, November 4

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m.—Discussion Meeting on "Advanced Methods of Energy Conversion—Magnetohydrodynamic Power Generation" organized by Dr. L. Rotherham, F.R.S.

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP (at the School of Pharmacy, 29 Brunswick Square, London, W.C.1), at 2.30 p.m.—Meeting on "Recent Developments in Microbiology in the Beverage Industries".

UNIVERSITY OF LONDON (at King's College Hospital Medical School, Denmark Hill, London, S.E.5), at 4.30 p.m.—Prof. H. Rahn (U.S.A.): "The Physiology of the Diving Women of Korea and Japan".*

INSTITUTION OF ELECTRICAL ENGINEERS (joint meeting with the Institution of Electronic and Radio Engineers, at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Selection of Topics for Research in Electrical and Electronic Engineering" opened by Sir Robert Cockburn, K.B.E., Dr. E. Eastwood, C.B.E., Prof. Sir Willis Jackson, F.R.S., and Dr. L. Rotherham, F.R.S.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. D. C. Phillips: "The Structure of Lysozyme". (Fifth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation).*

UNIVERSITY OF LONDON (in the Large Physics Lecture Theatre, Westfield College, Kidderpore Avenue, London, N.W.3), at 5.30 p.m.—Dr. J. Sicher (Czechoslovak Academy of Science): "Conformational Equilibria in Disubstituted Cyclohexanes".*

INSTITUTE OF REFRIGERATION (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 6 p.m.—Dr. H. N. Daglish: "Applications of Low Temperatures in Satellite Communications".

INSTITUTION OF MECHANICAL ENGINEERS, STEAM PLANT GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Relative Merits of Once-Through Versus Other Types of Boiler Circulation".

UNIVERSITY OF LONDON (at Queen Mary College, Mile End Road, London, E.1), at 6 p.m.—Prof. W. R. Sears (University of Cornell): "Steady Flow". (Second of four lectures on "Magneto-Fluid Dynamics").*

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the Brunel College Chemical Society, at Brunel College, Woodlands Avenue, London, W.3), at 7 p.m.—Mr. M. C. Hyde: "Collecting Information on the Chemical Industry".

Friday, November 5

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. R. W. Cannon, Mr. G. C. Rider and Mr. D. Wilkinson: "Operational Experience with Tropospheric Scatter Systems".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (joint meeting with the Fine Chemicals Group, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. W. Gerrard: "Studies in Boron Chemistry: Organic Analogues of Heterocycles".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. D. C. Phillips: "The Structure and Function of Lysozyme".

Saturday, November 6

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. Michael Boorer: "Rhinoecroses".*

Monday, November 8

PLASTICS INSTITUTE, PLASTICS PROPERTIES DISCUSSION CIRCLE (at the Mandeville Hotel, Mandeville Place, London, W.1), at 3 p.m.—Mr. R. A. Horsley: "Creep Properties of Thermoplastics".

SOCIETY OF CHEMICAL INDUSTRY, COLLOID AND SURFACE CHEMISTRY GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. G. P. C. Chambers: "The Colloidal and Surface Properties of Clay Minerals".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Hatfield College of Technology, Hatfield), at 6 p.m.—Discussion on "Is Laboratory Work Really Necessary?" opened by Dr. K. R. Sturley.

INSTITUTION OF MECHANICAL ENGINEERS, NUCLEAR ENERGY GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Fuel Element Behaviour in Gas-Cooled Reactors".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. A. G. Page: "Some Manufacturing and Processing Techniques in the Electronics Industry".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Lord Rennell of Rodd: "Heinrich Barth and the Opening Up of Central Africa".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RESEARCH ASSISTANT or RESEARCH FELLOW (graduate in physics or engineering) in THE DEPARTMENT OF CIVIL ENGINEERING, to work on problems of creep in concrete—The Registrar, King's College (University of London), Strand, London, W.C.2 (November 5).

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland

RESEARCH ASSISTANT (with a degree in mathematics, physics or chemistry and preferably some postgraduate experience) IN THE CHEMISTRY DEPARTMENT, to help in the devising and running of computer programmes for large problems in crystallography and theoretical chemistry under the supervision of Prof. D. W. J. Cruickshank—The Secretary of the University Court, University of Glasgow, Glasgow, W.2 (November 5).

ASSISTANT LIBRARIAN (university graduate and chartered librarian)—The Principal, Lanchester College of Technology, Priory Street, Coventry (November 8).

GRADUATE IN THE DEPARTMENT OF BOTANY for work on the physiology of insect-pathogenic fungi—The Registrar, University Senate House, Bristol, 2 (November 8).

RESEARCH ASSISTANT (preferably with a degree in engineering) IN THE DEPARTMENT OF MECHANICAL ENGINEERING IN THE FACULTY OF SCIENCE, to operate research equipment engaged in investigation of combustion in reciprocating engines, to help in analysis of observations, and to assist in the development of instrumentation—The Registrar, The University, Manchester, 13, quoting Ref. 185/65 (November 10).

LECTURER (graduate with some years of teaching experience at degree level, and preferably an interest in control systems work or in computing) TO ASSIST IN THE FACULTY OF TECHNOLOGY—The Academic Registrar, Enfield College of Technology, Enfield, Middlesex (November 12).

SPECIAL TERMINABLE ASSISTANTSHIP IN APPLIED PSYCHOLOGY (full-time post) with duties in either industrial or educational psychology—The Secretary, University College, Cork, Republic of Ireland (November 12).

SUPERINTENDENT (graduate in physics, preferably with experience of administration in industry, in the government service or in universities) OF LABORATORIES IN THE DEPARTMENT OF PHYSICS—The Registrar, University College of Swansea, Singleton Park, Swansea (November 12).

LECTURER IN MEDICAL PHYSICS—The Registrar, The University, Manchester, 13, quoting Ref. 188/65 (November 13).

READER IN STATISTICS AT THE LONDON SCHOOL OF ECONOMICS—The Academic Registrar, University of London, Senate House, London, W.C.1 (November 18).

LECTURERS/ASSISTANT LECTURERS (3) IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, University College of Wales, Aberystwyth (November 19).

CHAIR OF PURE MATHEMATICS—The Registrar, University of Newcastle upon Tyne, 6, Kensington Terrace, Newcastle upon Tyne 2 (November 20).

LECTURER IN PHILOSOPHY—The Secretary of the University Court, University of Glasgow, Glasgow, W.2 (November 20).

LECTURER IN SOCIAL ANTHROPOLOGY—The Secretary, The Queen's University, Belfast, Northern Ireland (November 20).

READER, SENIOR LECTURER, LECTURER OR ASSISTANT LECTURER IN PHYSICS IN THE SCHOOL OF MATHEMATICS AND PHYSICS—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 88G (November 20).

CHAIR OF ORGANIC CHEMISTRY at the University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 22).

CHAIR OF MICROBIOLOGY IN THE FACULTY OF MEDICINE—The Secretary, The Queen's University, Belfast, Northern Ireland (November 24).

CHAIR OF BIOCHEMISTRY—The Secretary of the University Court, The University, Glasgow (November 26).

CHAIR OF PHYSIOLOGY—The Secretary of the University Court, The University, Glasgow (November 26).

CHAIR OF SOCIAL AND PREVENTIVE MEDICINE at the University of the West Indies—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (November 29).

LECTURER (preferably with special interests and qualifications in terrestrial zoology with emphasis on entomology, especially the ecology of insects) IN ZOOLOGY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, November 30).

LECTURER (with a distinguished academic record and preferably with a research interest in one of the following fields: vertebrate physiology, embryology or tissue culture, cell biology, invertebrate zoology, other than entomology or marine biology) IN THE DEPARTMENT OF ZOOLOGY, School of Biological Sciences, University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 30).

LECTURERS (2) (one preferably theoretical reactor physicist with experience in modern computational techniques, and the other well qualified in the fields of fluid dynamics and heat transfer) IN THE DEPARTMENT OF NUCLEAR ENGINEERING—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (November 30).

LECTURER (Grade II) IN THE DEPARTMENT OF SOCIOLOGY—The Registrar, University Senate House, Bristol, 2 (December 1).

TEMPORARY LECTURER IN ZOOLOGY at the University of Western Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 4).

SENIOR FELLOW OR FELLOW; and a SENIOR RESEARCH FELLOW OR RESEARCH FELLOW IN THE DEPARTMENT OF MATHEMATICS, Institute of Advanced Studies, Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (December 6).

SENIOR LECTURER/LECTURER IN THE SCHOOL OF TEXTILE TECHNOLOGY, University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 12).

ENTOMOLOGIST (national of the United Kingdom or the Republic of Ireland, with a B.Sc. degree and preferably experience of African conditions) in Bechuanaland, to undertake a survey of the cotton, maize and sorghum pests and make recommendations as to their control—The Appointments Officer, Ministry of Overseas Development, Room 301, Eland House, Stag Place, London, S.W.1, quoting Ref. 213/19/06.

HEAD OF THE MATHEMATICS DEPARTMENT—The Master, Dulwich College, London, S.E.21.

LECTURER (with a good honours degree in zoology and preferably a higher degree)—The Registrar, Regional College of Technology, Leicester.

RESEARCH ASSISTANT IN THE DEPARTMENT OF AGRICULTURAL BOTANY for work on soil microbiology—The Registrar, University College of Wales, Aberystwyth.

TECHNICIAN/SENIOR TECHNICIAN IN THE DEPARTMENT OF BIOLOGICAL SCIENCES—The Secretary, Bradford Institute of Technology, Bradford 7.

OPTICAL ROTATORY DISPERSION OF A CHLOROPLAST PREPARATION. By Dr. Bacon Ee	573

(Continued overleaf)

Pye model 79 pH meter

The Pye Model 79 pH Meter is a new instrument based on new principles. Moderate in cost and robust in construction, it provides exceptionally good accuracy and discrimination. It sets new standards in this class of measuring instrument for stability and freedom from effects of power supply variations.

Based upon the Pye taut band microammeter and a specially developed transistorised power stabiliser, the Model 79 represents a major advance in general purpose pH meter design.

Ranges of measurement are 0 to 14 pH or +350 to -350 mV which are covered on a 7 inch scale. With a precise millivolt measuring range, the Model 79 has many applications as a high impedance millivoltmeter.

Facilities are provided for both automatic and manual temperature compensation for slope and zero shift throughout the range of 0 to 100°C. A calibrated buffer control can be used to indicate electrode deterioration. An output of 5-0-5 mV is available for a potentiometric recorder.

The Model 79 represents exceptional value for the modern chemical laboratory. Please write for full details.

Accessories

The Model 79 is supplied with an integral electrode clamp and a Pye Ingold combined glass/reference electrode which has a measuring range of 0 to 13 pH, a temperature range of -5 to +70°C (intermittent use to 100°C) and an electrical null point of $E_0.7$ for long-term stability. Additional accessories include a nickel resistance thermometer, a laboratory stand, a wide range of $E_0.7$ electrodes, etc

Clear Scale

The fascia of the Model 79 is at an ideal viewing angle and parallax errors are eliminated by the knife-edge pointer and backing-mirror on the meter. These features, combined with bold and well-defined calibration on the unusually wide scale, enable readings to be taken to 0.02 pH without difficulty.

Taut Band Meter

Special features of the Pye taut band, or pivotless, panel meter are its invulnerability to damage by heavy electrical overloads and its remarkable freedom from mechanical hysteresis, friction, sticking and deterioration. This gives very high sensitivity coupled with high accuracy and long term stability. The Pye suspension system employs strong incorrodible gold alloy strip

AGAROSE

A neutral galactose polymer obtained from Agar by a unique method using reagents, having no toxicity.

- * Negligible electroendosmotic properties.
- * High gel strength.
- * Non-toxic.
- * Minimum adsorption properties.

This product and many ENZYMES and RELATED BIOCHEMICALS of the highest possible integrity are produced entirely in our own laboratories.

PRECISION INSTRUMENTS

Polarimeter Model A

This instrument gives the highest degree of accuracy with divided circle on glass reading to 0.01 degree.

Circle centre on ball bearings • Easily removable trough • Divided drum replacing verniers • Stationary observation telescope • Circle reader enlarging image of scale • Slow motion adjustment always in action • Suitable, with additions, for measurement of rotatory dispersion.

This polarimeter has been supplied in large numbers both in this country and abroad and has always been acclaimed as being of advanced design and workmanship. Please ask for particulars "N".

THE ROAD TO PEACE

IT is now more than twenty years since the United Nations Charter was signed on June 26, 1945, at the San Francisco Conference, but although the anniversary was duly observed at San Francisco the dominant note was gloom rather than rejoicing. The problem of paying for past and future operations of the United Nations was still unsolved and was overshadowed by the continuing clash over Vietnam. Moreover, when on October 4 Pope Paul addressed the General Assembly of the United Nations, while neither of these had been resolved, the conflict in Kashmir had added to immediate anxieties.

Little wonder is it that there should be deep concern over the future of the United Nations, quite apart from any disappointment over failure to fulfil the high hopes entertained twenty years ago. While it is indeed appropriate that we should re-examine the structure of the Organization itself and seek the causes of weaknesses which in practice have developed, it is no less important to consider the changed circumstances and conditions in which the United Nations as an organization operates to-day, compared with those existing when it was established. It is true that the repeated failure to reach agreement on the revision of the Charter has proved a great hindrance and disappointment—this is especially so since, more clearly than the Covenant of the League of Nations, the Charter provides expressly for its own revision and modification in the light of experience.

Some of the changed conditions, indeed, are to be found in the United Nations itself. While China remains outside, the fifty nations represented at Dumbarton Oaks have grown to 114. The increase does not represent any substantial new areas or populations, but the proliferation of former dependencies into independent States with their own representation. The change, moreover, has been largely within the past decade: equatorial middle Africa is now represented, for example, by 30 independent Black States, and of these only two were independent before 1956, and 19 have been created since 1960.

It is natural enough that a strong spirit of nationalism should run among the new nations, but nationalism goes ill with international statesmanship and co-operation. Further, the new nations are inexperienced as yet in world affairs: perhaps the most serious charge that could be levelled against the former Colonial Powers is that they did so little, and that late, to prepare their dependencies for independence, even when, as with Britain, the goal had long been accepted. This comparative political immaturity of the new nations constitutes a great danger, as it can tend to political irresponsibility. The resources required to support the United Nations and make its policies effective remain, by and large, with the Great Powers.

That position has to be recognized and it should be noted, in passing, that this extends also to scientific policy, as has been recently emphasized (*Nature*, 201, 327; 1964). The influence of science, however, is even more significant in two other factors which have transformed the world since the San Francisco Conference. The first is the appearance of the nuclear bomb, which

was only used for the first time well over a month after that Conference. The decision to use the bomb introduced a new and unforeseen factor into the world situation, to which adequate thought was certainly not given by statesmen, although it would appear that some scientists did so. The second factor, and like unto the first, is the increasing pace of technological change of all kinds, of which a noteworthy instance is to be seen in the developments leading up to the *Early Bird* satellite transmission, which allowed Pope Paul's address to the General Assembly to be seen and heard, as he delivered it, thousands of miles away.

Development and change on this scale and at this rate must profoundly affect the relations between nations and the institutions through which those relations are organized. There has indeed been a remarkable growth in the activities of the various international scientific unions and the organizations through which those activities are conducted; so much so, that considerable expansion in the resources provided for the International Council of Scientific Unions is imperative if those activities are not to be circumscribed. The advent of nuclear warfare has intensified problems of disarmament; and its control, quite apart from all the psychological consequences and the problem of preventing the spread of nuclear weapons, is probably one of the most urgent and important problems of our times.

All this, however, has not made the United Nations redundant but more essential than ever if mankind is to survive. There is no other such viable international body reflecting the growing interdependence of the world and providing on an adequate scale the framework for the immense variety of inter-relations to-day. If it were dissolved it would be imperative to create immediately just such another institution as the alternative to world chaos. That this is realized is one hopeful feature in a gloomy situation.

Consider first, however, some of the consequences and implications of these scientific and technological developments of the past twenty years. The advent of nuclear weapons has increased the complexities of any steps towards disarmament, while at the same time it has undoubtedly had a restraining effect through the widespread realization that mankind cannot risk being involved in a nuclear war. If this problem could be solved the prospect of nuclear power has much to offer the world, though probably to a different extent in different parts of the world.

Here, however, we see that the real issue is the use which mankind makes of the new powers that have been placed at our disposal, whether they are used for good or for ill. The improvements in speed of travel and communication which, for example, enabled the Pope to reach New York so swiftly and allowed him to be seen and heard by millions when addressing the General Assembly, can be used to enable the Security Council to meet swiftly to deal with any emergency—if its members so desire. The techniques of television or broadcasting can be used thus for purposes of goodwill and to promote public understanding: they can equally be the sounding

board for propaganda, for misrepresentation and for fostering ill-will.

Finally, it should not be forgotten that the United Nations was founded deliberately as a democratic institution and such institutions make high demands on those who belong to them. They cannot function without discipline and fair-mindedness and a respect for the rights of others. The eruption into the General Assembly of a considerable number of those who, as yet, have had little experience of practising those qualities, of fostering the self-discipline, cannot but produce strains, misunderstanding, and failure to equate power and responsibility, and to forget that who wills the end must will the means. Time and experience are required to develop the qualities to use a democratic institution and to make it work effectively. If the demands made on the patience and sympathy of the old and more experienced democracies may sometimes seem heavy, if not excessive, it is at least encouraging that the new nations should be eager to use the United Nations as their main instrument and platform. That way there is at least hope.

If then the United Nations has ceased to be what its founders expected it to be, there is another side. In those twenty years of disappointment and frustration rather than failure have come the new opportunities provided by nuclear power, the exploration of outer space, the development of the backward parts of Africa and Asia, the acceleration, if not transformation, of communications; these opportunities which call imperatively for some sort of co-ordinating body have not been entirely missed by the United Nations. With some political failures there has been an immense advance in expert collaboration, within which to-day the International Council of Scientific Unions functions, and of which it is well aware. Some of this activity may be humdrum, but it is none the less vital, and the operations of the International Atomic Energy Agency, of the International Labour Organization, of the Food and Agriculture Organization, of the World Health Organization and of the United Nations Educational, Scientific and Cultural Organization are widely known. Some of them are indeed direct descendants of organs of the League of Nations and testify to the greater ease of international collaboration in technical as opposed to political matters. In fact, it is largely the influence of scientists that has led to what slender progress has yet been made in the control of nuclear weapons.

That is one important reason for welcoming the emphasis laid on technical assistance and the attention being given to the formulation of scientific policies for the developing nations. It is true that the spirit of the Lagos Conference on the organization of research and training in Africa in relation to the study, conservation and utilization of natural resources (*Nature*, 205, 1141; 1965) was deeply disappointing as well as unrealistic. It gave little indication that Dr. S. Dedijer's wise counsel was receiving the attention it deserved. Nevertheless, the fact remains that the developing nations are using the United Nations as a means of obtaining help from the richer countries without becoming open to political pressures and also of securing important reforms in the system of world trade.

In this last-mentioned connexion, the solidarity of some 75 nations at the United Nations conference on trade and development should not be overlooked, nor indeed the skilful diplomacy of Britain which contributed so much to avoid a split and to help the United Nations to retain its chance of being a principal instrument for

solving a large and explosive world problem. Since then, a most constructive report has come from the Advisory Committee on the Application of Science and Technology to Development. This body was established by the Economic and Social Council in January 1964 to follow up the work of the Geneva Conference in the previous year on the Application of Science and Technology for the Benefit of the Less Developed Countries (*Nature*, 207, 897; 1965). Here again are ample opportunities for constructive work, given goodwill and determined co-operation.

All this amounts to really impressive opportunities, and especially for Britain. Certainly, it should not be forgotten how much Britain has already contributed since the organization was founded. She is, in fact, the second largest contributor in cash and exceeds even the United States in the provision of experts who have served with the United Nations in the technical fields. This summer Britain gave a further lead with an unconditional gift of ten million dollars to help the United Nations out of its financial difficulties. However much more Britain might or should be doing, it is no service to peace to disparage or make party political capital of what she has hitherto done.

Where perhaps Britain—and others—have failed is in the tepid support given to the International Co-operation Year and the Development Decade. Half-way through that decade the target of 151 million dollars set in 1961 is still unachieved. Neither Britain nor the other members are really using the United Nations to do the jobs for which it was designed and where political obstacles are unsubstantial. That is why it is not enough for the emphasis to be placed on peace and peace-loving. We need not underrate the influence of Pope Paul's noble address, which may well extend far beyond his own Church or even Christendom. Where the way forward may seem at the moment to be blocked, we should be using to the full the opportunities for advance open elsewhere, and especially for bringing together in practical effort or consultation men and women of different nationalities.

Here the very rapidity of advance since the Charter was drafted at Dumbarton Oaks and then signed at San Francisco places a greater responsibility on the shoulders of the scientist and technologist. The opportunities which are theirs to-day are immensely greater, and though time may still be required before the effect of their co-operation reaches up to the highest levels, it can already begin to lay firm foundations for wider and deeper understanding. The Pugwash Conferences have at least indicated some of the possibilities. The challenge, moreover, is to professional institutions as well as to individual scientists and technologists. Their colleagues in the new nations will require the support and guidance which such institutions in the older countries can give if they are to organize themselves so as to influence effectively the Governments of their own countries and shape policy on lines that will promote the fullest development and use of indigenous resources. There are still large opportunities of personal service overseas which can contribute to international goodwill and understanding, and there is the responsibility that rests on all citizens to see that Britain's contribution to technical assistance and in other fields is generous.

If it is true that Britain should be leading the United Nations, part of that leadership must be contributed from the ranks of scientists and technologists. This is not to deny that realistic and constructive thought must

be given to the outstanding difficulties. Peace-keeping operations in the future will not always be agreed by everyone, and when some members have an objection to a particular operation, it is absurd and impractical to insist that they should be financially responsible for it. Moreover, while from time to time proposals will no doubt be advanced like those recently made for a world centre for medical research or an administrative staff college, which are of dubious merit on professional grounds, it should always be remembered that success in one place or field will lead to demands to use the United Nations and its agencies for others. All countries should be wary of squandering on dubious projects their resources and especially those of the United Nations, but where the effort is worth while, their response should be whole-hearted, imaginative and sustained. That is the road to peace.

NATURALLY OCCURRING PHENOLIC COMPOUNDS

Biochemistry of Phenolic Compounds

Edited by J. B. Harborne. Pp. xi+618. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1964.) 126s.

BIOCHEMISTRY of *Phenolic Compounds* is a literary symposium which enjoys the advantages, and suffers the defects, of the type. It has been possible to gather together contributions from experts in their respective fields, hailing chiefly from the United States and the United Kingdom, with two Australian authors. But these are of unequal merit, ranging from a rather scrappy and ill-arranged selection of examples to well-ordered short monographs. For this reason the work is unlikely to be read *in toto* by students, though it must prove of the greatest value to research workers in any of the special fields discussed.

Few recent extensions of the organic chemistry and biochemistry of natural products have been more surprising than those recorded in relation to plant phenolics. Perhaps it was too readily assumed that these regions had been rather fully explored and that, in any event, their inhabitants were not particularly interesting. If so, both assumptions were quite incorrect. The variety and significance of phenolic substances is now seen to be great indeed.

This change of attitude is primarily due to the introduction of new techniques, particularly the chromatographic separations, which have injected a new precision into descriptive subjects such as those treated under anthoxanthins and anthocyanins. The results of surveys made with the use of these clearer glasses have given us not only a more accurate idea of composition, but have also provided taxonomic data and helped notably with certain genetic problems.

Chapters of fundamental importance to the worker in the chemistry of natural products are those of Margaret K. Seikel on the isolation and identification of phenolic compounds in biological materials, of J. B. Harborne and N. W. Simmonds on the natural distribution of phenolic aglycones, and of J. B. Harborne on the natural distribution of phenolic glycosides.

The first-mentioned covers the topic from *A* to *Z* and is an admirable account of it. The only useful tip, known to me, and not here mentioned, is the formation of good crystalline derivatives by combination of polyhydric phenols with *N*-methylstrychnine or *N*-methylbrucine.

The two chapters of which the editor is author and part-author are central to the theme, since without them the edifice could not have been constructed. The brilliant

pioneering work of Bate-Smith at Cambridge must be recalled in this connexion. An example among the anthocyanins will serve to show the kind of progress made. Many of these pigments are well-characterized by their properties, including habit of crystallization. This is the case with chrysanthemin and pelargonin, to take two clear examples. But mecocyanin, isolated by Willstätter and Weil (1917) from flowers of *Papaver rhoeas* L., is by no means so well defined. Its discoverers showed that it hydrolyses with formation of cyanidin and two molecules of glucose. When chrysanthemin was synthesized, it became clear that mecocyanin must be a cyanidin 3-bioside, because its colour reactions were as near as possible identical with those of chrysanthemin (cyanidin 3-glucoside). Accordingly in 1934 the 3-cellobioside, maltoside, lactoside and gentiobioside were synthesized. These pigments closely resembled each other but showed slightly different distribution ratios between partially miscible solvents. The gentiobioside and mecocyanin came closest. But later the chromatography of carefully hydrolysed mecocyanin showed that the sugar was sophorose, that is 2-glucosidylglucose instead of the 6-derivative. Sophorose was first isolated in 1940.

The advances in chromatographic technique led at once to their application to genetic problems and, as R. E. Alston shows, the increase of visibility on the road, while clearing the way, has opened up fresh vistas. It cannot, however, be claimed that much progress has been made towards a real understanding of the basis of heredity in these fields. The facts have been clarified and arranged and this is an important preliminary to future generalization.

Useful summaries of what is known are also contained in two chapters on the metabolism of phenolics. This is, however, a part of general biochemistry and it seems somewhat artificial to concentrate on the phenolic group in all cases.

More specific to the subject-matter are the four highly interesting chapters on aspects of the biosynthesis of phenolic substances. The major pathways, recorded by A. C. Neish, are those starting from acetate (malonate), shikimic acid (or both) and the isopentane route. The part played by each is evaluated as the result of application of various experimental methods, of which the most important is the use of isotopic tracers. The general reader as well as the specialist will be fascinated by the tale that is unfolded. S. A. Brown describes the use of these and other methods to elucidate the biosynthesis of tannins and lignin. The work mentioned has not only solved the problem set but also has reflected light on the structure of these important substances themselves.

The final chapters on phenolics in relation to their pharmacology, physiology, pathology, and even taste are doubtless of high interest but look as if they had been added for the sake of completeness.

This compendium, with some faults and many virtues, is primarily of interest to chemists and biochemists and will be a standard work of reference for them for many years to come. Its production reaches the high standard which we have been led to expect from the publishers. There are few errors, the structural formulae being especially clear and accurate. ROBERT ROBINSON

HIGH-PRESSURE PHYSICS

Physics of High Pressures and the Condensed Phase
- Edited by A. van Itterbeek. Pp. xv+598. (Amsterdam: North-Holland Publishing Company, 1965.) 140s.

THE growing interest in high-pressure studies has been reflected in recent years in a number of books, but there is no text dealing in such detail with the particular aspect chosen in this collection of articles by different

authors. The title of the book is somewhat misleading since most of the chapters deal with systems at low temperatures and moderately high pressures, and not all the topics are relevant to the condensed phase, for example, the articles on the spectra of gases. The standard is high, at the level of appeal to research workers. Since the chapters appear to be independent, with little cross-reference, they will be reviewed *seriatim*.

Chapter 1, by L. Deffet and L. Lialine, on "High Pressure Techniques in General", is limited to a rather perfunctory account of methods of closure and manometric devices, followed by a good summary of theory and observation on the elastic equilibrium and plastic flow of thick-walled cylinders. Ultra-high pressure techniques are not considered.

The mechanical properties of metals at low temperatures are treated by J. F. Watson, J. L. Christian and A. Hurlich in Chapter 2. This field has recently become important in relation to cryogenic work on missiles, hydrogen bubble chambers, etc. After a brief summary of theoretical principles the major part of this chapter consists of a detailed report on the behaviour of various alloys.

Chapter 3, by J. M. H. Levelt Sengers, consists of a critical appraisal of the experimental methods for the determination of the equation of state of gases at low temperatures and at pressures greater than a few atmospheres. An unusual feature is the report, about a page for each, on ten research centres throughout the world. A repeat is given of an account of manometric devices discussed in Chapter 1.

Chapter 4, by O. Verbeke and A. van Itterbeek, on "The Equation of State of Gases", is confined in the experimental section to work done at Leuven, Belgium (already reported on two pages in Chapter 3). This section is followed by a useful survey of data for the liquid vapour pressures of hydrogen, neon, oxygen, nitrogen, argon and methane and valuable compilations of thermodynamic data. In correlating these data more use could have been made of the principle of corresponding states. The final section comprises a summary of the various theories of the liquid state, including quantum liquids, and some comparison with observation (the authors state (p. 155) that the Monte Carlo method has not yet been applied to the liquid phase).

J. W. Stewart (Chapter 5) tackles the properties of "solidified gases" (that is, those substances which are gases under normal conditions) at high pressure and at temperatures less than 200° K, covering melting curves, compressibility, phase equilibria (surprisingly different for CH₄ and CD₄), etc. There is a useful summary of theories of melting.

After Chapter 4, with 23 pages on the theory of liquids, it is somewhat surprising to revert to this topic in Chapter 6 by A. Münster. However, the treatment is more sophisticated, although relaxation phenomena are omitted. Considerable attention is directed to the Monte Carlo method. As is usual in this rather unsatisfactory field, examples are limited to simple non-polar molecules.

Liquid and solid helium are rightly given separate chapters (respectively by R. H. Sherman, Chapter 8, and J. S. Dugdale, Chapter 9), since the quantum behaviour and choice of isotopes give a rich field of study. The bizarre properties of helium are excellently treated in these two chapters; the most compressible of solids, helium is often taken as a model substance from which the properties of other substances may be inferred in inaccessible regions. J. S. Dugdale rightly warns research workers against too slavish an adherence to this principle. Much remains to be done in this field; for example, why is an open body-centred cubic structure adopted near to 0° K?

"The Velocity of Sound in Dense Fluids" by W. van Dael and A. van Itterbeek (Chapter 7) and "Transport Phenomena" by O. van Paemel (Chapter 10) treat kinetic phenomena in fluids, often at low temperatures. The former chapter has the more detailed theoretical analysis.

Chapters 11 and 12, respectively by B. Oksengorn, H. Vu and B. Vodar on "Optical Aspects of High Pressure Investigations" and by J. P. Colpa on "Induced Absorption in the Infra-red", might have been combined; indeed the last-mentioned author devotes some space to the work of Vodar *et al.* already treated in Chapter 11. These chapters are concerned with molecular interactions in gases and their effect on spectral transitions, and such optical topics as the effect of pressure on the refractive index, rotatory dispersion, etc., are omitted.

The final two chapters on superconductivity (M. Levy and J. L. Olsen) and the electrical properties of metals and semiconductors (G. Landwehr) are, perhaps, somewhat out of place in this volume since the range of pressure is so much greater, extending to 600,000 atm. for measurements of conductivity, and only the former chapter is confined to low temperatures; nevertheless they are both useful summaries.

The treatment throughout is authoritative and the production excellent (although an author index would have been useful and the subject index is inadequate). In spite of the repetition, the occasional infelicities in the English, and the high price, this book can be recommended to all high-pressure workers, as it is packed with useful information, although much of the book is concerned with a rather limited range of molecules, the lighter inert gases and a few others of simple structure. The region of moderately high pressure, with which most of the book is concerned, provides a very satisfying study, since high precision is possible in the measurements and theory need not be unduly stretched. The editor is to be congratulated on bringing together this collection of articles which should stimulate further research—much remains to be done, for example, on the critical state.

R. S. BRADLEY

SPACE DYNAMICS

Dynamics of Rockets and Satellites

Edited by G. V. Groves. Pp. xi+313. (Amsterdam: North-Holland Publishing Company, 1965.) 80s.

THIS volume is a record of the lectures at the international summer school on the "Dynamics of Rockets and Satellites" held at Cambridge in July 1963. The book begins with a short section on the equations of motion of a rocket, by D. S. Carton. This is nicely balanced in the next chapter by an account of an actual design, the European Launcher Development Organization's launching vehicle, by H. G. R. Robinson. Chapters 3 and 4 return to mathematics, with J. M. J. Kooy discussing the dynamics of controlled rocket launching, and E. Stiefel dealing with many-body problems, as applied to interplanetary and circumlunar flight. In Chapter 5, R. H. Giese outlines the essentials of satellite tracking and orbit determination.

The next two chapters are concerned with orbital perturbations. M. J. Davies derives Lagrange's planetary equations and shows how they can be used for determining the effect of the atmosphere on orbits. W. M. Kaula propounds an elegant and generalized method for evaluating gravitational perturbations and also touches on the effects of radiation pressure, which have so far proved resistant to elegant formulation. The theme of the final two chapters is the rotational motion of a satellite about its centre of gravity. W. G. Hughes discusses attitude stabilization, including the torques acting, the methods of sensing attitude and control actuation. The subject of the last and longest chapter, by A. J. Sarnecki, is the dynamics of rigid-body rotation: a thorough and illuminating exposition of vectors and tensors is followed by a description of the rotational motion of typical satellites.

Most of the individual contributions are of a high standard and the complete book forms a valuable conspectus of space dynamics. In organizing the conference

Dr. Groves chose both subjects and lecturers judiciously; and in editing the book he has managed to avoid many of the perils of multiple authorship, though some overlapping among the contributions inevitably remains. The book would form a sound basis for an academic postgraduate course on space dynamics: it is, however, too advanced for an undergraduate course, and some of the contributions are of greater academic than practical interest. The book is well printed and the layout is pleasing.

D. G. KING-HELE

MATERIALS AT HIGH TEMPERATURES

Thermal Stress

Edited by Dr. P. P. Benham and Dr. Russell Hoyle. Pp. x+382. (London: Sir Isaac Pitman and Sons, Ltd., 1964.) 90s. net.

Plenum Press Handbooks of High Temperature Materials

No. 1. Materials Index

By Peter T. B. Shaffer. Pp. xx+740. 17.50 dollars.

No. 2. Properties Index

By G. V. Samsonov. Translated from the Russian. Pp. xii+418. 22.50 dollars.

No. 3. Thermal Radiative Properties

By W. D. Wood, H. W. Deem and C. F. Lucks. Pp. 470. 17.50 dollars. (New York: Plenum Press, 1964.)

THERMAL Stress is a symposium based on a conference held at the Imperial College of Science and Technology, London, in 1962, on the effects of temperature on the stresses within a body and on the properties of the component materials. It is divided into three parts, the first giving a résumé of the theoretical aspects of thermal stress, the second concerning thermal cycling and creep but also including a chapter on materials at high temperature, and the third detailing some industrial examples of thermal stress problems and their solution.

Like most published symposia, the book can be criticized for a lack of balance and completeness in dealing with its subject. The treatment of the high-temperature properties of materials, for example, is cursory, occupying only two out of twenty chapters, and would probably have been better omitted altogether. Regarded as a collection of papers, however, the book performs its function of presenting the thinking and results of those active in the field.

The *Plenum Press Handbooks of High Temperature Materials* provide, in three volumes, a wealth of data on those metals and ceramics that are used or usable at elevated temperatures. Volume 1 lists more than five hundred different ceramic materials such as carbides, borides, nitrides, sulphides, phosphides, silicides, and oxides, giving for each such structural, chemical, mechanical, thermal and physical data as could be culled from the sources consulted, these being mainly U.S. Government reports. The data available about a given substance vary enormously and the reader may be frequently disappointed in not finding the information for which he seeks. The book does not claim, however, to be exhaustive, and the author, Dr. P. T. B. Shaffer, is to be complimented on providing a good start to the classification of high-temperature materials and their properties.

Volume 2 in the series is the translation of a Russian work by Prof. G. V. Samsonov in which data on refractory materials are classified according to properties rather than materials. It has a brief but useful introduction followed by data on structure, composition, density and thermal stability. Chapter 2 deals with thermal properties of all kinds, and the succeeding chapters cover in turn the electrical, optical, mechanical, chemical and refractory

characteristics of these materials. Oxides are not covered in this book as they have been dealt with elsewhere. A final set of tables gives examples of the application of refractory compounds. This work is more exhaustive than Volume 1 with more than 1,300 references compared with less than 500 in the latter, but the two volumes are clearly complementary and together provide an indispensable source of collected data.

Volume 3 deals with the thermal radiative properties of high-temperature materials and contains data on titanium and its alloys, stainless steel, iron, nickel and cobalt and their alloys, chromium, columbium, molybdenum, tantalum and tungsten with their alloys, coated materials of many kinds, ceramics and graphites. For each material the data provided include a graph of emittance (spectral or total) against temperature (given unfortunately in degrees Fahrenheit) together with information on the methods and conditions of measurement and, of course, the reference. In many cases graphs of normal spectral emittance against wave-length at some reference temperatures are also supplied. There are introductory chapters on "Fundamentals and Definitions" and on "Methods of Measurement", the latter being a brief survey backed up by thirty references to the literature.

E. H. ANDREWS

THE WORLD OF FISH

A Draught of Fishes

By Dr. F. D. Ommañney. Pp. 254+23 photographs. (London: Longmans, Green and Co., Ltd., 1965.) 36s. net.

SOME twenty-three thousand species of fish inhabit the waters of the world, more than those of all the other vertebrates put together. Their habitat covers more than 70 per cent of the surface of the globe, and ranges from the sunshine and surf of the shore to the black death-like calm of the abyss. The fishes—using the word in its widest vernacular sense—are the oldest class among the living vertebrates, and have had many million years more than the other classes to evolve in adaptation to their infinitely varied environment; though time has apparently stood still for many of them since the Carboniferous, natural selection must yet be acting on the combinations and permutations in the gene pool of others. This great host, not only of species but also of individuals, provides a subject well suited to such an accomplished writer as Dr. Ommañney, who has spent many years in research on improving the yield of commercial fisheries in many parts of the world.

The book opens with a chapter sketching in the oceanographic background of the fish's world and of the fisheries that exploit its wealth. The various forms of fishing gear and their methods of use are then described, from the latest European V-D trawl, and the ships equipped with radar and fish-finding echo-sounders that use it, to the simple traps and fish-weirs so commonly used on tropical coasts—not that simple "fixed engines" are extinct in Europe, for the wicker putchers still used in the Severn Estuary can be little different from the fish traps no doubt fished there when Julius Caesar first landed, or perhaps in neolithic times or even earlier. Dr. Ommañney intersperses his chapters on such subjects as shoaling, the colours of fishes, the abyss and the inshore waters, fresh waters, and the plankton feeding fishes, with others describing the different researches on specific fisheries, and the exploratory voyages undertaken in their prosecution, with which he has been associated. The last are among the best in the book, for his vivid style conveys the essential flavour of life in a trawler on the northern grounds off Iceland and Bear Island or with the tunny men of Brittany in the Bay of Biscay. The fisherman's world is

poles apart from the ordered routine of the landsman, who can have no inkling of its distance from his way of life; but, rough and uncomfortable as the life of a fisherman may be, the ceaseless struggle against the unending hostility of the elements and the ever-changing beauty, probably seldom consciously appreciated, of their infinite variety bring a primitive satisfaction that drives men to sea again and again in spite of all sea-born vows to swallow the anchor for good.

The last two chapters discuss the possibility of farming the sea, and the future of fisheries and man. The artificial cultivation of fresh-water fishes has a long history and a bright future, but no more than the first tentative experiments have yet been made in cultivating marine fishes—the artificial rearing of fry, the transplantation of young fish to rich feeding grounds, and the fertilization of semi-enclosed areas of the sea. One wonders whether pouring the untreated sewage of much of northern Europe into the North Sea can have had any effect in making it one of the finest fishing grounds of the world, or whether the suggested ploughing of the bottom to stimulate the production of the benthos which forms the diet of so many food fishes could increase the harvest. The human population explosion results in an ever-increasing demand for food protein; Dr. Ommanney speculates about the possibilities of satisfying the demand with the products of the sea, and on the effects of the radioactive wastes that we dump into the depths in 'leak proof' containers when inevitably they do leak. "There seems to be no limit to what man may achieve with his technology and his formidable know-how. . . . Nevertheless, the abuse of his own know-how threatens his very existence and already casts a lengthening shadow which reaches even to the uttermost depths of the sea."

Dr. Ommanney's book will be enjoyed equally by the professional biologist and by the layman for whom it is primarily intended. It is well illustrated with coloured and monochrome photographic plates and with numerous line drawings of excellent quality. There are, however, several howlers that a more careful final revision might have avoided; the Weberian ossicles have certainly not become the hearing bones of the ear of higher animals (p. 45), the claspers of elasmobranchs are not, as Agassiz mistakenly supposed, "pressed together so that their grooved inner faces form a tube along which the sperm flows" but are inserted singly into the female passage (p. 73); no carefully measured Basking shark has reached "a length of 40 feet", 30 ft. is nearer the mark (p. 79); the marine lancelet *Branchiostoma* is not the same creature as the "sand lance", which is the sand eel *Ammodytes* (p. 197), and Fig. 19 purporting to show gill rakers is a failure. These regrettable lapses form the few shadows that contrast with the brilliance of the rest of the book.

L. HARRISON MATTHEWS

PURPOSE AND MEANING OF A UNIVERSITY

The Modern University

By Prof. G. L. Brook. Pp. 192. (London: André Deutsch, 1965.) 25s. net.

PROF. G. L. BROOK, Smith professor of English language and medieval English literature in the University of Manchester and a Pro-Vice-Chancellor, has written an account of university problems to-day similar to that of 'Bruce Truscott' some twenty years ago. There is the same ease of expression but more authority as well as balance about the whole book. It is a little disappointing, therefore, that the production of such an admirable book should fall considerably short of what was possible in the midst of the War at a third of the price.

Prof. Brook's opening chapter gives a brief discussion of the purpose of a university, and this, together with the

following chapter on entrance requirements, and an appendix on the organization of a modern university, should make plain to prospective students, and their parents, much that sometimes perplexes them. In the succeeding chapters he writes on students and on lectures and tutorials with a refreshing sanity and humour, as well as with balance; his remarks could be disconcerting to the extremist. In general, however, the most valuable chapters in the book are those which deal with books, with professors and lecturers and with academic freedom. The first will be welcomed by those urging more generous provision for university libraries. Librarians should be encouraged by the clear understanding shown of their difficulties and also of the problem of book-buying by students. The second corrects a misleading impression conveyed by 'Bruce Truscott' and should assist in giving a clearer understanding outside the university of the problems involved in the relations between research and teaching. Together with the final chapter on expansion, it brings down to earth some of the wilder statements and arguments of those who seek to determine university expansion by service to political doctrine rather than by reference to public needs and the real nature or purpose of a university.

For the chapter on academic freedom alone *The Modern University* would be welcome. Prof. Brook's exposition of the issues, including those aspects arising from the relations of university teachers with one another and the amount of freedom that students should enjoy, could scarcely be improved. He sees the danger at present as so real that our universities will do well to keep the very considerable freedom they have, and he believes that the chief threat comes from well-disposed persons, genuinely interested in education but who value other things more highly. The threat from outside is largely the result of the success of universities, and Prof. Brook shows clearly how the ear-marked grant can act in this way. The greatest single external threat to academic freedom to-day is the dependence on the State for so large a proportion of the university's income. The greatest internal threat is indifference among university teachers, or the practice of 'taking it for granted'; here he includes the fact that the scholar is reluctant to take his or her share in administration. Nor does he believe that the University Grants Committee will by itself suffice. For the defence of academic freedom it is necessary to convince public opinion that the State ought not to exercise the power it possesses. He adds that accordingly maintenance of a high standard of administrative efficiency under academic control is a most important safeguard of academic freedom, that many important decisions in university affairs should not rest entirely in the hands of one man, and that students, as well as teachers, have rights to be safeguarded.

Prof. Brook closes this chapter on a note of responsibility addressed particularly to the university teacher. That is the keynote of his final chapter, which includes many frank but uncomfortable words for student as well as teacher and administrator. He brings a timely pragmatic point of view to bear on the whole problem of expansion, arguing that the important question is whether potential students can profit by a university education sufficient to justify the considerable expenditure of time and money involved. He reminds us of the limits set to expansion by the availability of university teachers of the right calibre, and that the number of students who could profit from some other form of higher education is very much larger than the number of those whose proper place is in a university. He has constructive suggestions for breaking down existing barriers between school and university teaching. The whole tone of the book is a complete answer to those who accuse the university of being conservative, out of date and unwilling to face modern opportunities. Prof. Brook is to be congratulated on a most readable and timely book. R. BRIGHTMAN

MIMICRY AND THE EVOLUTION OF ANIMAL COMMUNICATION

By DR. W. WICKLER

Max-Planck-Institut für Verhaltensphysiologie, Seewiesen u. Starnberg, Germany

DURING the hundred years since Bates's discovery of mimicry in 1862, countless numbers of mere suggestions, experimental analyses and intense discussions about the evolution, the consequences and even the existence of mimicry have been compiled. This literature will not be reviewed here. Instead, I would like to suggest that the study of deceptive signals and a re-defined mimicry-concept offer a strict method for reconstructing the phylogeny of social signals and that we have to study mimicry carefully with respect to the evolution of animal communication. This makes it necessary to reconsider the concept of mimicry under the aspects of modern ethology.

As early as 1890, Poulton drew a distinction between defensive or protective mimicry, as illustrated by wasp-like beetles, moths, flies, etc., in which the mimic is preyed on by a predator, and aggressive mimicry, in which the mimicking species is itself the predator and preys on some animal which is not afraid of the mimicked species. This is the case, for example, in the mimicry between the wrasse, *Labroides dimidiatus*, and the blenny, *Aspidontus taeniatus*¹, which I have studied in greater detail², because *Aspidontus* mimics even behavioural characters of its model. *Labroides* removes ectoparasites from the bodies, fins and buccal and gill cavities of other fish. These fish often show special 'invitation postures' and the cleaner occasionally displays in a sort of dance in which the caudal fin is spread and the posterior part of the fish oscillates up and down. Size, form, coloration, and even the dancing of the cleaner are simulated by *Aspidontus*, who thus succeeds in eliciting the invitation posture from other fish. Being a fin-eater, however, he then attacks instead of cleaning them.

Another case classified as aggressive mimicry is that of the eggs and young of parasitic birds which mimic the signals serving as species recognition marks and/or eliciting brood care in the host species. The orchids of the genus *Ophrys*, the flowers of which mimic the social releasers of female Hymenoptera and elicit sexual behaviour in the males, fall into the same category; they offer no nectar but only the opportunity for pseudocopulation to the male insects, who thus transfer their pollen.

Essential for both types of mimicry is the deceived partner, one of the normal reactions of which is 'misused'. This may be a flight reaction or a blocking of feeding in protective mimicry, and quite a number of different reactions in so-called aggressive mimicry. Often a feeding reaction is exploited as by the angler fishes, but many other behaviour patterns may also be exploited, such as the need for being cleaned (by *Aspidontus*), the copulatory reaction (by *Ophrys*), or the care of the young (by the various brood parasites). These examples show (1) that in spite of some existing mimicry-definitions no predator need be involved in a mimicry system, and (2) that the terms 'defensive', 'protective', and 'aggressive' are inadequate to cover the diversity of signals and reactions misused in mimicry. Moreover, though colours and forms of organs and movements as optical markers are

most conspicuous to us, scents and sounds may be mimicked also, as Kullenberg³ has shown in some orchids which even imitate the sexual odours of hymenopteran females, and as Nicolai⁴ has shown in the whydahs that imitate the calls and songs of their host species. Therefore, instead of referring to pseudosematic or deceptive colours we should rather speak of deceptive stimuli or signals. Since the deceived partner may be responding as predator, or mate, or parent, or cleaning customer, it will be called simply the reacting signal-receiver or the receiver.

Mimicry, then, can be defined in the following way:

(1) A signal is emitted by two different signal-senders (S_1 , S_2) which have at least one signal-receiver (R) in common that reacts similarly to both of them.

(2) One of the senders is called a model, the other a mimic (and the whole model-mimic-receiver system a case of mimicry), if it is profitable (+) for the receiver to give the reaction to one of the senders, but unprofitable (-) to react in the same way towards the other. That means that if the signals from the two senders could be distinguished by the receiver, individual experience and/or selection would favour different reactions. This is shown, for example, by the cleaner mimicry: *Aspidontus* deceives mainly younger fish, at least some of which then learn to distinguish between model and mimic and to avoid the latter. Constant learning by the signal-receiver results in a strong selection pressure against detectable differences between model and mimic.

(3) It suffices to define model and mimic as follows: the sender the signal of which elicits a reaction which has negative selective consequences for the receiver (which would be selected against if given to this sender only), that is the sender by which the receiver is deceived, is called the mimic, the other the model. These relationships may be symbolized thus:

$$S_1 + R - S_2$$

The selective consequences for the receiver of responding to the model are always positive (the reaction would disappear if it were at all unfavourable to the receiver). The mimic—if a living creature—always has a selective advantage (+) in releasing the reaction from the receiver (an unfavourable signal will disappear, too). If S_2 is the mimic, our formula automatically turns into:

$$S_- + R - +S_2$$

(It is, of course, a matter of convenience whether one chooses the reaction or the signal as a reference unit; one could equally as well have considered the selective consequences for the receiver in receiving the signal from both senders and for them in emitting it.)

The selective consequence for the model eliciting and obtaining the reaction from the receiver may: (a) be absent, if the model is an inanimate object; (b) be negative, if the model is a worm, for example, usually eaten by the receiver and mimicked by another predator in order to catch the receiver; (c) be positive as in the wasp (who remains alive if it is avoided by the predator), or in the

cleaner (who feeds on parasites harmful to other fish), or in those hymenopteran females, the male-attracting signals of which are mimicked by certain orchids.

The simple definition given here overcomes the difficulties arising from some recent characterizations of model and mimic. It is irrelevant which of the two was first present. Poulton postulated that model and mimic should be sympatric. They need not be sympatric, however, but must only have a signal-receiver in common: a model might be in Africa and its mimic in Europe (or vice versa), functionally connected by a migratory bird. Another postulate was that mimics must be less numerous than their models. This means, correctly stated, that the receiver has to meet the mimic less often than the model, and is based on the assumption that one experience with the model has the same after-effect, the same 'weight' as has one with the mimic. This need not be so, however; in fact, the negative experience seems usually to be the stronger one. This negative experience may result from an encounter with the model (a wasp) or with the mimic (for example, the *Aspidontus*). In the latter case one would suppose that the mimic in fact has to be less numerous than the model², but there might very well be more wasp mimics than wasps.

Assuming that a predator learns to reject a conspicuously coloured protected animal from a single experience and—as in imprinting—without forgetting it, then the model-species has to sacrifice one individual per predator regardless of how many mimics there may be. Of course, the protective power of the model, that is the advantage of being its mimic, is reduced with increasing numbers of mimics, because the predator will eat larger numbers of them before his first encounter with the model. Furthermore, if the signal receiver reacts towards the signal via an 'innate releasing mechanism' (IRM) which cannot be modified by experience, each individual of the receiver species will be fully deceived by the mimic even if it never meets a model (this seems to be the case in some of the female-mimicking orchids). Thus, whether or not the reaction is eliminated in phylogeny depends on its usefulness to the species in other contexts.

In all cases the selective value for the mimetic characters increases, among other things, with the number of successful deceptions from one deception per receiver on. The orchids (and other mimicking flowers) are the only mimics known to me, however, that need at least two deceptions per receiver—in order to undergo cross-pollination. The disadvantage for the deceived species should, therefore, be minimized, as it is by the orchid-flower allowing only attempts at copulation and thereby parasitizing the strong reward offered by true copulations with a female. So, finally, the type of reaction given by the receiver has also to be taken into consideration.

Signal Standardization and Müllerian Mimicry

It will have become clear already that even fundamental characteristics of mimicry are determined mainly by behavioural properties of the signal-receiver and that, therefore, a precise knowledge of the identity of the receiver and a thorough ethological study of its behaviour are indispensable for the understanding of mimicry. Additional arguments for this will come from the following considerations which will show, moreover, that mimicry is not sharply distinct from, but gradually merges into, other sender-receiver communication systems.

First, since palatability is a matter of degree, there might possibly exist a whole range of increasing distastefulness even in the mimics, model and mimic in the extreme case being equally unpalatable and sharing the same warning coloration. This stage is called Müllerian mimicry which in our notation would be:

$$S_1 + +R + +S_2$$

This is no true mimicry, however, since nobody is deceived

and it is impossible to differentiate between model and mimic. But there is still another difficulty: all individuals of a given wasp-species look alike and all are equally protected. Yet this is not usually called Müllerian mimicry, simply because the signals were not independently, convergently evolved. Since, however, the male wasps have no protective properties⁵ but retain their group-specific warning coloration, this clearly is Batesian mimicry, although model and mimic are conspecifics and their signals are homologous. Convergence of the signal-characters, therefore, is essential only for the so-called Müllerian mimicry, and thus Müllerian mimicry is distinguished from other cases of signal standardization.

Summing up, the typical (Batesian) mimicry merges into Müllerian mimicry if the difference between the selective consequences for the receiver of reacting similarly to S_1 and S_2 diminishes; and by homology of the signal characters it further merges into general signal standardization and such problems as that of typical intensity⁶.

Secondly, insects may be protectively coloured by resembling a wasp or a twig, the first case being called mimicry, the latter mimesis. The difference again lies within the signal-receiver. If the mimetic signal does not release any reaction in the receiver, it falls under mimesis. This is illustrated by De Ruiter's neat experiments with stick caterpillars which by virtue of their close resemblance to twigs are protected against insect-eating birds⁷. As soon as there are too many caterpillars, however, the bird develops an interest in them and then also attacks real twigs. In our notation this would be:

$$S_1 - +R - -S_2$$

S_1 being the caterpillar, S_2 the twig and (as shown by R 's minus) the mimic. If then one positive experience of R with the caterpillar had the same weight as a negative one with a twig (and the signal remains unchanged) it will depend on the relative abundance of caterpillars and twigs whether all twigs are mistakenly exterminated or R 's feeding reaction towards twig-like objects disappears, changing our formula into:

$$S_1 + -R + +S_2$$

so that now the caterpillar (S_1) becomes the mimic.

This again illustrates the importance of R 's reaction to decide correctly which is the model. This example further shows how easily an object (here the twig) may quite involuntarily become a mimic. This is further well illustrated by the common 'farming' relationship between ants and aphids. The siphones and cauda of the aphid correspond respectively to the bases of the antennae and labium of the ant, and the aphid's abdomen is mistaken by the ants for the head of a fellow ant, thereby eliciting the food-begging response which is identical with milking. Saturated ants in their turn even try to feed the abdomens of the aphids⁸. Aphid-species with reduced abdominal siphones use their hind legs as antennae-dummies, the movements elicited being originally defensive movements. This is exactly the way in which mimicry arises. Mimetic characters need not have evolved under the selection pressure of mimicking; in fact, their earliest evolutionary stages could not even have been brought about in this way. All the cases that I have been able to study so far could be traced back to an incipient stage of deceptive resemblance borne as a pre-adaptive atelic by-product of pre-existing species-specific characters, thus providing a point of attack for selection pressure. The 'dancing' of *Aspidontus* mentioned already originated as an up-and-down movement of the head which occurs in all blennies during a conflict between the tendencies to approach an object and to flee from it. This may occur in stationary fish as nodding or be superimposed on swimming, becoming a sort of dance. These movements usually have a special social meaning in threat or court-

ship, but in *Aspidontus* they are socially meaningless and so could become specialized as an interspecific signal². That the characters of the mimicking signal secondarily evolve further under natural selection is usually admitted, though sometimes doubted, as is even the mere existence of positive selective consequences resulting from the deception of a communication partner. The simple reason for these doubts is that in order to analyse and understand a given mimicry-system one needs a rather comprehensive knowledge of morphology, behaviour, ecology and their mutual relationships in animals usually belonging taxonomically to different classes of the animal kingdom (for example, wasps (Hymenoptera)—flies (Diptera)—insect-eating amphibians, reptiles, birds and small mammals). To reconstruct the evolution of such a complicated communication system, one also needs a detailed acquaintance with a larger group of forms related to each of the animals involved. But, in fact, we are far from having all these data.

Intra-specific Mimicry

That positive selective consequences do result from the deception of a communication partner is, however, shown automatically by deceptive signals that have evolved intraspecifically. In the small characoid fish *Corynopoma rrisei* the operculum of the male is elongated into a thin whitish stalk terminating in a small blackish plate. This is raised during courtship together with the operculum, and by its jerky movement resembles an edible object. This the female tries to grasp, and so comes into close contact with the male. Here mimic and receiver belong to one species. There are other cases (for example, the mimicking orchids or the parasitic whydahs) in which model and receiver belong to the same species. However, the safest conclusions can be drawn from intraspecific mimicry, in which model, mimic and receiver all belong to one and the same species. The best-known such example is the use of egg-dummies by the males of mouth-brooding *Haplochromis* species³, a group of African cichlid-fish. These dummies are conspicuous yellow or orange spots near the base of the anal fin which precisely resemble the eggs of the particular species. They are displayed to the female during courtship and during fertilizing and elicit her reaction of snapping up eggs. During courtship they make the male more attractive to the female. In spawning they assure fertilization of the eggs, which are taken into the female's mouth immediately after they have been laid and before the male is able to fertilize them: in snapping at the 'egg spots' with her lips, the female inhales the sperm, thus fertilizing the eggs within her mouth.

Here the specific female behaviour pattern of gathering eggs into the mouth is elicited alternately by model and mimic several times in succession with intervals of only about 1–2 sec, and within the same spawning pit. This offers ideal opportunities for comparison, since environmental factors as well as the internal states of the animals remain roughly constant. Moreover, the undeceived and the deceived reactions together form a functional unit, the deception clearly having positive selective consequences for the species. Nevertheless, the receiver's minus towards the mimic in our formula remains correct, since the individual clearly is deceived.

Another example of intraspecific mimicry is offered by some Old World monkeys, especially the Hamadryas baboon, the females of which during oestrus display conspicuous swellings of the ano-genital region, which is presented to the males as an invitation to copulate. Presenting, however, serves still another social function, since it is used by both sexes as an important appeasement or 'greeting' ceremony towards higher-ranking group members. The males, in order that their presenting be as effective as that of the females, imitate the females' swelling by a conspicuously red coloration of their hind-quarters as a dummy oestrous-marking^{10,11}.

The Theoretical Importance of Deceptive Signals

To reconstruct the evolution of a case of intraspecific mimicry as a special communication system is relatively simple for one needs detailed knowledge of but one rather narrow taxonomic unit. This is important, because mimicry is an indispensable step in studying the evolution of animal communication. This study usually starts from conspicuously elaborated signals, which postulate a signal-receiver interested in them. The receiver will practically always have undergone a special moulding towards optimal receiving of the signal. One must, however, follow up the mutual adaptations of the sender and the receiver separately. This is easily done so far as the evolution of a reaction or a receiving mechanism is concerned in all predators that try to find their prey, and in all prey-animals that try to escape an approaching predator. The 'suppression' of signals may be studied in predators that try to sneak up on a prey unnoticed. However, the 'elaboration' of a signal (in which the receiver must, of course be interested) can only be studied without co-adaptive interference from the receiver where the sender has a one-sided interest in the signal, which then can only be an imitation of either a signal developed in their common interest by the receiver and another signal-sender or a signal emitted by another signal-sender and only made use of by the receiver in his own interest. Both cases, by the definition given, are called mimicry. An additional advantage is that we know the model as the final stage towards which the mimic will evolve (so far as the signal characters are concerned), thus indicating the trend in evolution that is still operating and that probably will further elaborate the mimetic signals.

Finally, we may briefly consider social signals in general. It is legitimate to treat them as structures, even if they are motor-patterns¹². Evolutionary 'new' structures are merely modifications of preceding structures; "the emergence of a new structure is normally due to the acquisition of a new function by an existing structure"¹³. In the same way the egg-signal in *Haplochromis*, which originally belonged to the context of brood-care, has taken over the new functions first of bringing the gametes together and, secondly, even of bringing the parents together; and it has given rise to a new structure, the egg-dummies. If all signals have emerged during evolution at one time or another as 'novelties' one may question for what they might have been mistaken *in statu nascendi* by their respective signal-receivers. To treat signals generally as having passed through an original mimetic stage renders studies of mimicry valuable tools for students of the phylogeny of signals and of animal communication. In this way I have found that another cichlid fish, *Tilapia macrochir*, deposits spermatophores: I considered the male's conspicuous genital tassel as an imitation of something which finally turned out to be the spermatophore¹⁴. It should be added, however, that it is not as yet quite clear whether the spermatophore truly is the model, because both tassel and spermatophore may be mimics of a still unknown model. Finally, there is the possibility of chain-mimicry, that is, of secondarily mimicking a mimic; however, research in this field is still in a very early phase.

THE JUVENILE HORMONE*

By SIR VINCENT WIGGLESWORTH, C.B.E., F.R.S.

Department of Zoology, University of Cambridge

IN choosing this topic for the opening address to the third conference of European Comparative Endocrinologists, I had in mind the consideration of the juvenile hormone in general terms—as an agent with properties that must be of interest to all endocrinologists. I shall not therefore attempt a complete or specialized survey of this very complex subject, but will select only a limited number of points for discussion.

A Morphogenetic Hormone

The juvenile hormone is a morphogenetic hormone—one of the most outstanding morphogenetic hormones known. The existence of a hormone responsible for maintaining larval characters was first revealed by the fact that decapitation in young *Rhodnius* larvae causes premature metamorphosis¹. Parabiosis showed that this hormone was freely circulating in the blood; and by removing progressively more and more of the anterior parts of the head from the insects used in the parabiosis experiments, it was shown that the hormone came not from the brain but from the corpus allatum—an endocrine organ that buds off from the ectoderm at the base of the mouthparts and comes to lie just behind the brain¹. This conclusion was confirmed by the implantation of corpora allata from young (3rd- or 4th-stage) larvae into 5th-stage larvae. These 5th-stage larvae then moulted not into adults but into giant 6th-stage larvae².

The juvenile hormone acts directly on the epidermal cells responsible for laying down the cuticle at moulting: restricted local application of the hormone results in a restricted local patch of larval cuticle in an otherwise adult insect³. It is possible, for example, to produce adult insects with one larval wing³. The self-same cell has the capacity for laying down larval cuticle or adult cuticle. That is most clearly shown in the sensory bristles or hairs: the trichogen cells which form the bristles persist from one stage to the next; in the presence of a large amount of juvenile hormone these cells lay down larval-type bristles; in the absence of the hormone they lay down adult-type bristles, and with intermediate amounts of juvenile hormone, bristles of intermediate type are developed⁴. Under natural conditions intermediate forms do not commonly occur. There is a strong tendency for the insect to develop either larval or adult characters.

Experiments by many authors have shown that the juvenile hormone controls metamorphosis in insects of all kinds. In holometabolous insects, which have a pupal stage between the larva and the adult, the juvenile hormone again controls the morphogenetic change: a large amount of the hormone ensures retention or re-development of larval characters; absence of the hormone results in metamorphosis to the adult; the presence of a very small amount of juvenile hormone leads to the appearance of the pupal form⁴. This result not only confirms the importance of the juvenile hormone in controlling morphogenesis, but it illustrates in a most striking way a point often made by C. M. Child: that the same inductor substance can evoke totally different results depending on its concentration or the timing of its action.

Here again intermediate forms rarely occur in Nature. But they can be induced experimentally: if the corpus allatum is removed from the last-stage larva of the honey-bee⁵ or of the giant silkworm *Hyalophora*⁶ the supply of

juvenile hormone falls below the level necessary to produce the pupa, and monstrous forms intermediate between pupa and adult develop. Some caterpillars pass through a regular succession of morphological stages in successive instars. These forms also seem to be regulated by levels of juvenile hormone secretion—but the detailed evidence for this has not yet been fully worked out⁷.

The Nature of Hormone-controlled Metamorphosis

It has long been recognized that the effect of the juvenile hormone is to control the realization or suppression of inborn potencies. In other words, it brings about 'gene switching'. In this regard it resembles the inductor substances which control morphogenesis in different parts of the body during differentiation; and the factors which lead to the differences in form of different individuals in environmentally induced polymorphism⁸. Indeed, there are a number of polymorphic changes in which there is evidence that the level of juvenile hormone activity may itself be involved, notably (i) the change over from the 'solitary' to the 'gregarious' form in locusts⁹; (ii) the switch from apterous to alate forms among parthenogenetic aphids¹⁰; (iii) the production of the soldier caste in termites^{11,12}.

Just how and where the juvenile hormone is acting is not known. Twelve years ago I wrote "it is a matter for discussion whether the simultaneous inheritance of the dual potentialities for larval and adult differentiation within these societies of cells is by way of the nucleus or cytoplasm or both"¹³. Eight years ago I submitted that the juvenile hormone "controls the manifestation of alternative genetically controlled forms" and I suggested that "it is possible to conceive it as being concerned in the regulation of permeability relations within the cells—in such a way that the gene-controlled enzyme system responsible for larval characters is brought increasingly into action when the juvenile hormone is present"¹⁴.

The position is unchanged to-day—except that tissue-specific puffing patterns in the chromosomes of *Drosophila*¹⁵, on one hand, and the theories of enzyme induction in bacteria as developed by Jacob and Monod¹⁶ *et al.*, on the other, render us much more prepared to accept the idea of a primary action of the hormone at the level of the gene. Experimental evidence has yet to come.

Reversal of Metamorphosis

The question was early raised whether the genetic system responsible for the production of larval characters was still capable of re-activation by the juvenile hormone in the adult insect. In other words, whether metamorphosis can be reversed. Of course, this can only be tested by making the adult moult again by exposing it artificially to the moulting hormone.

In general it can be said that in most adult tissues it is not possible to induce any reversal of metamorphosis. But there are certain undoubted examples of such reversal: in the abdominal cuticle of *Rhodnius*¹⁷ and of *Oncopeltus*¹⁸, in the thoracic cuticle of the earwig *Anisulabis*, where the 'ecdysial line' characteristic of the larva can be re-induced in a moulting adult¹⁹, and in the integument of Lepidoptera where larval cuticle can be re-induced in fragments of pupal and imaginal integument^{20,21}.

Reversal of metamorphosis is an abnormal phenomenon. There has been no selection for its occurrence and it is

* Substance of an opening address to the third conference of European Comparative Endocrinologists held in Copenhagen during August 1965.

not surprising that it occurs with difficulty. Likewise the production of stages intermediate between the normal stages in metamorphosis is an abnormal phenomenon and selection will have acted against it.

Time of Action of the Juvenile Hormone

The most effective moment for exposing the tissues to the juvenile hormone seems to be just before they begin the synthetic activities characteristic of the larval stage. Hormone administered too early is less effective—presumably because it is broken down in metabolism before the time for its action has arrived^{22,23}.

But there are certain effects which are induced in the cells long before they become manifest. A very small dose of juvenile hormone administered soon after feeding in the 5th-stage larva of *Rhodnius* has no effect on the type of cuticle laid down: normal adult cuticle is produced over the abdomen. But it does have the effect of ensuring the survival of the trichogen cells (almost all of which normally break down and disappear from the dorsum of the abdomen during metamorphosis), so that an excessive number of hairs appears on the abdomen of the adult²³.

The juvenile hormone has a comparable effect on the survival of the thoracic gland. The thoracic gland (the source of the moulting hormone) normally undergoes autolysis in *Rhodnius* within 24 h after moulting to the adult. This is a response to some hormonal factor in the newly moulted adult. But if the gland has been exposed to juvenile hormone during the pre-moulting period, it does not respond in this way and fails to undergo autolysis²⁴. (The breakdown of certain muscles after metamorphosis in the silkworm *Hyalophora cecropia* has recently been shown to be regulated in much the same way²⁵.)

Influence of the Juvenile Hormone on Behaviour

In certain caterpillars, behaviour is different in the final stage before pupation than it is before moulting in the earlier larval stages. The wax moth *Galleria* spins a tough cocoon before pupation, a flimsy web before a larval moult²⁶. The sphingid *Mimas tiliae* crawls down the tree-trunk to the soil before pupation, but rests on the foliage before each larval moult²⁷. These differences result from the presence or absence of juvenile hormone and are attributed to a direct effect on the nervous system. But the possibility remains that they could result from a nervous feed-back effect from other organs, for example from the distended silk glands.

Gonadotrophic Effects of the Juvenile Hormone

Secretion of the juvenile hormone ceases in *Rhodnius* in the 5th-stage larva before metamorphosis, but begins again in the adult. The hormone is then necessary for yolk formation in the female and for the full activity of the accessory glands in the male, which serve to produce the spermatophores to enclose the sperm². In *Hyalophora cecropia*, in which the eggs are developed during the pupal stage, very little juvenile hormone is secreted in the adult female, but large amounts are produced in the adult male²⁸, which secretes a succession of spermatophores.

The precise nature of the gonadotrophic effect of the juvenile hormone is uncertain. The position is complicated by the fact that in some insects the secretion from the neuro-secretory cells in the brain seems to be more important than the juvenile hormone in ensuring yolk production. In the case of *Rhodnius*, G. C. Coles²⁹ concluded that the juvenile hormone acts on the fat body cells and serves to activate those components of the gene system which lead to the synthesis of the specific proteins that are discharged into the blood and are taken up by the oocytes and added to the yolk. In the male locust, *Schistocerca*, T. R. Odhiambo³⁰ considers that the juvenile hormone activates the many systems concerned in protein synthesis in the nuclei of the accessory glands.

Metabolic Action of the Juvenile Hormone

The juvenile hormone is often said to be a 'metabolic hormone'—by which is meant that it sets going metabolic processes, either of synthesis or of combustion, whether or not these are required for the working body. I am sceptical about the existence of metabolic hormones in this sense; I think they are unphysiological. I fancy that in most cases of this kind the hormone is setting in motion some physiological process, and the observed changes in metabolism are feed-back effects. (But, of course, abnormally large doses of hormones may have an abnormal pharmacological effect on metabolism which has little relation to their normal influence in the body.)

A well-known example of a metabolic effect of the juvenile hormone is the accumulation of reserves of fat and glycogen in the fat body of the grasshopper *Melanoplus* when the corpora allata are removed³¹. But Odhiambo³² has shown that in the locust *Schistocerca* the juvenile hormone acts on the central nervous system and causes continuous activity. After allatectomy the insect continues to feed normally but it becomes inactive; consequently reserves pile up. The accumulation of reserves is not a feed-back effect from the gonads; the same effects are seen in males with or without their accessory glands.

In the blowfly *Calliphora*³³ and in the cockroach *Leucophaea*³⁴ the corpora allata are necessary to maintain the normal high level of oxygen consumption. But here again the juvenile hormone may be initiating some physiological activity (perhaps the synthesis of ovarian proteins) which demands increased oxygen consumption. In these cases it is not known whether nervous or muscular activity is changed. In the bug *Pyrhocoris* the effect of the corpus allatum on metabolism is seen only if the gonads are present: it appears to be a feed-back effect from the activated ovaries which are demanding nutrients³⁵. Likewise in *Rhodnius*, the accelerated rate of digestion in the presence of the corpus allatum is a feed-back effect from the developing ovaries³⁶.

In *Leptinotarsa* the adult female goes into diapause when the juvenile hormone is absent or the corpora allata are removed. The rate of metabolism falls to a very low level and egg development ceases. In this state the thoracic muscles and their mitochondria degenerate almost completely. When juvenile hormone is supplied everything is restored: the beetles become active, the ovaries develop, muscles and sarcosomes are fully regenerated³⁷. The metabolic effects are profound—but just where the juvenile hormone is acting is not known.

It is, of course, self-evident that hormones can influence the body only by bringing about chemical changes in the cells. In this sense they are always 'metabolic hormones'. Within a few hours the moulting hormone restores nucleoprotein synthesis in dormant epidermal cells of *Rhodnius*¹⁴; the juvenile hormone seems specifically to induce the synthesis of yolk proteins in the fat body of *Rhodnius*²⁹; as Gilbert³⁸ has recently shown, the juvenile hormone will induce the fat body of the cockroach *Leucophaea* to synthesize ovarian lipids. But these, and many similar effects, are elements in a pattern of development evoked by the hormone. They are not simply quantitative changes in metabolism unrelated to growth requirements—as is commonly implied by the expression 'metabolic hormone'.

Chemical Nature of the Juvenile Hormone

The large accumulation of juvenile hormone in the adult moth of *Hyalophora cecropia* provided a source of active extract. Ether extracts from the abdomen of the male moth gave an orange-coloured oil rich in juvenile hormone activity²⁸. This material was utilized to develop methods of assay^{3,22} and methods for concentrating the active principle by countercurrent separation²². These procedures were applied to extracts from many sources

and have shown that material with roughly the same partition properties, and with juvenile hormone activity, is widely spread throughout the animal and plant kingdoms: in the tissues of invertebrates and vertebrates, in higher plants, some bacteria and yeasts.

The material extracted from two of these sources, namely from the excrement of the mealworm, *Tenebrio*, and from yeast, was examined chemically by Schmialek³⁹; the active principle was isolated and shown to be a mixture of *trans-trans*-farnesol and its aldehyde farnesal. The question arises whether the natural juvenile hormone in the insect has any relation to farnesol or is of a totally different nature.

At the present time the answer to this question is not known. Farnesol will certainly reproduce all the morphogenetic and gonadotrophic effects of the juvenile hormone in *Rhodnius*⁴⁰. It is particularly effective if its stability is increased by blocking the alcohol end of the molecule in the form of an ether (for example, farnesyl methyl ether) or as the farnesyl acetone⁴¹.

In the form of the methyl ether, a 0.06 per cent solution of the active *trans-trans* isomer is far more effective than the natural extract from *cecropia*. 1.2 µg will cause a partial retention of larval characters in *Rhodnius*—a dose of 5.2 µg/g of body-weight²³. In *Antheraea*, 20,000 µg of the natural extract from *cecropia* will cause a partial retention of pupal characters—a dose of 4,000 µg/g of body-weight⁴².

By repeated partition with methyl alcohol, chromatographic separation on silicic acid columns, followed by the crystallization of impurities, a 'non-crystalline fraction' has been isolated which will produce this same effect in *Antheraea* at a dose of 5 µg, that is, 1 µg/g of body-weight⁴². Accepting these results at their face value this product is about five times as effective as farnesyl methyl ether in *Rhodnius*.

Further attempted purification by gas-liquid chromatography leads to heat destruction of the natural substance, but one fraction isolated in this way had an activity twelve times that of the 'non-crystalline fraction'⁴². Meyer, Schneiderman and Gilbert⁴³ report similar results, showing pyrolytic breakdown of the material in the gas-liquid chromatography column, but with some highly active fractions. Røller, Bjerke and McShan⁴⁴ have isolated a well-defined active substance which is certainly not farnesol.

The significance of these results is uncertain. Assay methods for material that is exerting its action over a period of many days of development, and which is continuously being broken down in metabolism, have no very precise meaning. (By modifying slightly the means of administering the material I have recently repeated the results on *Rhodnius* as described here with half the earlier dose, that is, with about 2.5 µg of the active isomer of

farnesyl methyl ether per gram of body-weight.) At the present time farnesol derivatives are the only compounds of known chemical composition with juvenile hormone activity. They were identified as the substance with juvenile hormone activity in the extracts of non-insect material. They have been found in the extracts of *cecropia* and other silkworms. Until other known compounds have been isolated, I am inclined to hold to the provisional hypothesis that the active group in the juvenile hormone is indeed the triple isoprene unit of farnesol, and that this exists in the natural hormone in some form that has not yet been defined.

OBITUARIES

Dr. H. R. Marston, F.R.S.

DR. HEDLEY RALPH MARSTON died in Adelaide on August 25, the day before his sixty-fifth birthday, and the day on which he was to retire from his post of chief of the Division of Biochemistry and General Nutrition of the Australian Commonwealth Scientific and Industrial Research Organization. He was one of three brothers born in Bordertown, South Australia; his father was a Civil Servant. The family moved to Adelaide where he attended Unley High School. A school-fellow, Mark (now Sir Mark) Oliphant, attained high scientific distinction and remained a life-long friend. In 1934 Marston married Kathleen Nelly Spooner, who survives him. They had no children.

There were two rather unusual features about Marston's career. From first to last he held appointments in Adelaide; and his first degree was conferred on him *honoris causa*, some thirty-three years after his first academic appointment. When an undergraduate student of chemistry in the University of Adelaide, he chanced to meet, during a country walk, a stranger with whom he fell into conversation. This proved to be Brailsford Robertson, newly arrived to take up the chair of physiology and biochemistry in the University. Within a few days, Marston had joined Robertson's department as demonstrator, and during the next seven years assisted him in organizing the teaching of biochemistry and physiology in the University. In 1926, Marston sat for the B.Sc. examination in biochemistry and physiology and headed the honours list; but he was

then so fully engaged in research and teaching that he was unwilling to retrace his steps in order to comply with the regulations necessary for taking a degree. This rather orthodox entry to the academic world in some degree calls that of Gowland Hopkins, who was first an articulated pupil to a public analyst: he moved to Guy's Hospital Medical School, where he took a medical degree, but only a time snatched from research and teaching commitments. It may be that academic life will be the poorer now that insistence on 'paper qualifications' has made such unusual shortcuts all but impossible. During these early years, Marston received much help from Archibald Watson, a professor of anatomy, of whom he always spoke with affection, as well as from Brailsford Robertson.

His first paper adumbrated the importance of the mitochondria as centres of enzyme activities—a concept since fully confirmed. In other papers he showed for the first time that the mammary gland of the monotreme echidna indeed secrete true milk, described the first micro-method for the determination of guanidine and methyl guanidine, and published work on the sterol isolated from the 'giant toad stool'.

In 1927 he joined the Division of Animal Nutrition of the (then) C.S.I.R., newly formed under Brailsford Robertson. He was in charge of the Division between Robertson's death in 1929, and the appointment of Sir Charles Martin as chief in 1930. A close bond grew up with Martin, and when he returned to England in 1932, Marston was appointed chief nutrition officer, and placed in charge of the Nutrition Laboratory, which became part of the Division of Animal Health until 1944, when the Division of Biochemistry and General Nutrition was established with Marston as its first chief. During this period the researches of Marston and his colleagues covered a wide field and had important practical applications. While he always insisted that advances in practice depended on an understanding of the underlying natural phenomena, he nevertheless tried to ensure that the practical means of applying scientific principles were available. Among other subjects, the work included valuable fundamental researches on the animal's requirements for protein for the manufacture of skin and wool and on the special need for sulphur-containing amino-acids (now, but not then, common knowledge). He early observed the effect of copper on keratinization and hence on the quality of wool. Other work dealt with the requirements of the sheep for phosphorus, and of the effects on it of thyroidectomy.

In 1936 he was invited by Hopkins to spend a year in the Biochemical Laboratory, University of Cambridge. There he continued his work on carbohydrate fermentation by ruminal micro-organisms, and interested Joseph Racker in general problems of ruminal function, with most fruitful results.

During the Second World War he furnished, with his colleagues, valuable information to the Army on available human rations, and compiled highly useful dietary tables. After the War he worked on the basic problems of energy transactions in ruminants. The work for which he is most widely known can be traced to its beginnings in 1933, when he became interested in 'Coast disease'. Considerable stretches of land, among them the 'ninety mile desert' near his birthplace, would support neither useful crops nor domestic stock. This was (wrongly) ascribed to phosphorus deficiency. Marston and his colleagues showed that phosphorus was adequate, but that there was a lack of cobalt and copper, and in certain areas of zinc, and that traces of such elements would permit the normal growth of both plants and animals. These fundamental discoveries proved the key to the solution of difficulties encountered by agriculturists and pastoralists in other continents besides Australia, and gave impetus to the conception of the importance of heavy metals in biological processes which is still growing. Marston was able to show that cobalt was effective only after it had been incorporated into vitamin B₁₂ by ruminal

micro-organisms, and that at least one of its functions in the body was that of co-enzyme in certain isomeric changes. The story must now be left to other hands to unfold: that there are further chapters is certain.

Marston was widely read, and widely travelled, both in Europe and the United States, with a fund of reminiscences of people and places. In 1957 he was elected D.Sc. *honoris causa* (his first degree) by the Australian National University, and in 1959 to a D.Sc. of the University of Adelaide *ad eundem gradum*. He was invited to lecture on the work of the Division to the Royal Society of London in 1948, and was elected Fellow in 1949. In 1951, Sir Mark Oliphant and he were active in the foundation of the Australian Academy of Sciences, of which they were original members. He numbered among his close friends not only scientific colleagues such as Martin, Hopkins, Rivett, Oliphant and E. V. McCollum, but also famous artists, and leaders in the industrial world such as W. S. Robinson in Australia and J. L. Pratt and Robert Kleberg, jun., in the United States. Perhaps from such contacts sprang some of his sympathy with practical problems.

E. G. HOLMES

Prof. Arthur Holmes, F.R.S.

ARTHUR HOLMES, emeritus professor of geology and mineralogy in the University of Edinburgh, died on September 20 at the age of seventy-five at his home in Putney. His brilliant research on the wider problems of geology has earned him his place as one of the great Earth scientists of the century.

Holmes was born at Hebburn, near Newcastle-upon-Tyne, in 1890. He graduated at the Imperial College of Science and Technology in 1910 and undertook an expedition to Mozambique in 1911. Here an attack of blackwater fever nearly ended his career (there was in fact an announcement of his death in the local paper), but he came back to rejoin the staff of Imperial College until 1921. He then joined the Yomah Oil Co. in Burma as chief geologist; but, fortunately for the future of geological science, he returned in 1924 to become head of the newly created Department of Geology in the University of Durham, which under his leadership rapidly gained an international reputation for petrological research. In 1943 he was appointed regius professor of geology in the University of Edinburgh, which was honoured with his occupation of the chair for thirteen years, and with his presence as emeritus professor for six years after he retired in 1956.

Prof. Holmes has exercised a profound influence on almost all branches of geology, not only through his own remarkable researches but also by his beautifully written text-books and the stimulation of the research qualities of his students. His output of publications has been prodigious—nearly 200, including several famous text-books such as *The Age of the Earth*, *Nomenclature of Petrology*, *Petrographic Methods and Calculations* and *Principles of Physical Geology*. He has made a great number of contributions to our knowledge of the geology of many parts of the world, from his home district in the north of England to Africa, India and elsewhere; but the descriptive aspect of his work has been, far more than with most men, merely a prelude to his remarkable work on the wider genetic problems of the science. He went deeply into the major questions of the origin of igneous rocks, partly in association with his accomplished and eminent wife, Dr. Doris Reynolds. He was never a man to shun controversy, and his work on the origin of the alkaline rocks of Africa and elsewhere, on the thorny problems of granites and their associates, on the origin and development of magmas, and on the role of metasomatism in rock genesis, has broadened the vision of igneous and metamorphic petrologists all over the world.

During his school-days, Holmes's inquiring mind had questioned the magic date for the Creation, 4004 B.C., in Archbishop Ussher's chronology for the book of *Genesis*,

and in the sixth form his interest in geology was awakened by an enlightened schoolmaster who encouraged him to read Kelvin and Suess. He was thirteen years of age when Rutherford realized that radioactivity might provide a means for determining the actual ages of minerals, and he was an undergraduate at Imperial College when this idea bore fruit, and Boltwood (using lead ratios) and then Strutt (using helium content) approximately dated a number of uranium-bearing minerals. Working in Strutt's laboratory, Holmes became one of the pioneers in this field, and since that time he has been one of the leaders in applying the results of radioactive methods to the dating of rocks. He took a major part in the construction of a geological time-scale in terms of millions of years—considering both post- and pre-Cambrian rocks and the age of the Earth itself.

Holmes's major work was not confined to igneous and metamorphic petrology and geological time. His contributions to the geophysical aspects of geology are classic: the nature of orogenic and epeirogenic activity, convection currents in the Earth's mantle, continental drift, radioactivity in geology—one could go on for a long time listing the aspects of geology to which he has made major contributions. In fact there is scarcely a main branch of the subject, other than palaeontology, with which his name is not associated. Much of his thinking was on the grand scale, applied to the broad philosophical aspects of the Earth sciences.

Holmes's distinguished career received international acclaim. He was elected Corresponding, Foreign or Honorary Member of the Geological Societies of America, Belgium, and Stockholm, and the Academies of Science of the United States, Sweden, the Netherlands, and France. He was awarded the Murchison and Wollaston Medals of the Geological Society of London, the Penrose Medal of the Geological Society of America, the Fourmarier Medal of the Royal Academy of Belgium, and the Makdougall-Brisbane Prize of the Royal Society of Edinburgh. In 1964 he shared with Prof. P. Eskola of Helsinki the Vetlesen Prize of Columbia University, New York, for outstanding achievement in science relating to "a clearer understanding of the Earth, its history or its relation to the universe". He was a Fellow of the Imperial College of Science and Technology and an Honorary Doctor of Laws of the University of Edinburgh.

In spite of many years of poor health, Holmes continued his creative work until the end. The second edition (largely re-written and greatly enlarged) of his *Principles of Physical Geology*, published this year, is a masterpiece of lucid writing and shows a breadth of knowledge and vision which few men possess.

Those fortunate enough to have known Prof. Holmes found him a quiet man of extraordinary charm and unfailing kindness, and will remember with affection and gratitude the help and advice which he gave so readily. In 1914 he married Margaret Howe, and they had one son. His wife died in 1938, and he later married Dr. Doris Reynolds, herself a distinguished geologist.

F. H. STEWART

Sir Ernest Thomas Fisk

WITH the death of Sir Ernest Thomas Fisk at his home in Sydney on July 8, at the age of seventy-eight, the world lost a man who made a conspicuous contribution to the development of wireless communication.

Born at Sunbury-on-Thames, England, on August 8, 1886, he entered the Marconi Company's training school in 1906 and came to Australia in 1911 as resident engineer of a branch which the Company had opened in Sydney. He submitted to the Australian Government proposals for the setting up of a number of wireless stations, but his proposals were not accepted.

In the same year, the Australasian Wireless Company was formed with Australian capital to acquire and operate

the patent rights of the Telefunken system. Two years later, Amalgamated Wireless (Australasia), Ltd., was inaugurated, and the rights of the Marconi and Telefunken systems were acquired. Fisk became technical and general manager, and in 1917, managing director.

In England in 1916 Fisk arranged with Marconi to conduct a series of tests, and in the following year erected an experimental receiving station at Pymble near Sydney. Tests were conducted there with the view of determining the best type of circuit to use for long-wave long-distance reception.

Later, Fisk transferred the station to Wahroong another Sydney suburb, and began experiments with the Caernarvon station in Wales early in 1918. When the tests were satisfactory, arrangements were made for public demonstration of direct wireless communication between England and Australia.

Messages to Australian newspapers were sent from Caernarvon by the then Australian Prime Minister, Mr. W. M. Hughes, and the then Australian Minister for the Navy, Sir Joseph Cook, who were in England at that time. These, the first direct wireless messages between the two countries, were received at Fisk's Wahroonga station and delivered to the Sydney Press.

Later, the experimental receiving station was transferred to Koo-wee-rup, in Victoria, where the scope of the work was extended, new apparatus was installed and continuous day and night observations made of signals from all high-powered stations in Europe and the United States.

The Koo-wee-rup experiments established that wireless waves from England to Australia followed the course of the greatest darkness—a discovery which ultimately was of immense value when aerials for the short-wave service were being designed.

As an outcome of successful experiments, Fisk, on behalf of Amalgamated Wireless in conjunction with the Marconi Company, in 1921 offered to establish a direct wireless service between Australia and Great Britain and to transmit messages at rates one-third less than existing cable charges. The proposal, which was strongly opposed by exponents of a relay system, found champions in Mr. W. M. Hughes and General Smuts of South Africa. They opposed the relay system and made it clear at the Imperial Conference in 1921 that their respective countries would proceed with direct communication.

Strengthened by the positive attitude of Mr. Hughes, Fisk persisted with his advocacy of a direct service, and in March 1922, on behalf of Amalgamated Wireless signed an agreement with the Australian Government under which the Company was to establish and maintain direct wireless communication between Australia and the United Kingdom and Canada, and to assume control of existing coastal and island wireless stations. The Government acquired 50 per cent of the shares in the Company plus one to give it a bare majority, the remainder of the shares being held by private shareholders.

Fisk was not daunted by the refusal of the British Government to grant a licence to the Marconi Company to erect a high-power station in England. The experiments were continued, and in January 1924 the first transmission of short-wave signals was received from the Marconi station at Poldhu, Cornwall. In August of that year, a fresh agreement was entered into with Amalgamated Wireless to erect short-wave transmitters with directional aerials to provide service to Great Britain and to Canada when corresponding stations were built in those countries. Fisk's foresight and initiative were rewarded in 1927 with the opening of the Beam Service to the United Kingdom and in 1928 to Canada.

Commenting that the Company had fought against powerful opposition, Royal Commissioners who investigated broadcasting within Australia reported to the Federal Parliament in 1927 that the Company, Fisk and his officers were "entitled to great credit for the establish-

ment of the Beam system". They commented that "... was largely due to the technical ability and persistence of its managing director that it ultimately prevailed and that Australia has the benefit of an up-to-date and extremely rapid means of communication with Great Britain...".

In the field of Australian broadcasting, Fisk was a pioneer. He gave the first demonstration of wireless telephony in Australia in August 1919. Gramophone music played into a wireless transmitter was received in

the lecture room of the Royal Society of New South Wales, several city blocks away. A year later he arranged a complete broadcast concert to a large audience in Parliament House, Melbourne.

He was foundation president of the Institution of Radio Engineers Australia and one of the earliest members of the Wireless Institute of Australia. He continued as chairman of directors of Amalgamated Wireless until 1945.

L. A. HOOKE

NEWS and VIEWS

Royal Society Research Professorship: Prof. W. S. Fyfe

PROF. W. S. FYFE, professor of geology in the University of California, Berkeley, has been appointed to a Royal Society research professorship. He will work at the University of Manchester and will take up his appointment in January 1966. Prof. Fyfe, who was born in New Zealand and has held appointments at the University of Otago and the University of California, is well known for his work in the field of experimental mineralogy and petrology.

Anglo-French Military Aircraft: Ministry of Aviation:

Mr. J. A. Hamilton

MR. J. A. HAMILTON, formerly of the Royal Aircraft Establishment, Farnborough, has been appointed project director for the *Jaguar* strike/trainer and the variable-geometry combat aircraft to be developed jointly by the United Kingdom and France. He will be responsible within the Ministry of Aviation for the management of the two projects, acting in concert with corresponding directors in the French Direction Technique des Constructions Aeronautiques. Mr. Hamilton was educated in Scotland at Penicuik and Lasswade Secondary Schools; he graduated in engineering from the University of Edinburgh in 1943 and then joined the Marine Aircraft Experimental Establishment. He was engaged initially on the development of anti-submarine weapons and later became responsible for all flight research within the Establishment. In 1951 he joined the Aerodynamics Department of the Royal Aircraft Establishment and in 1952 he was appointed head of the Free-flight Division. During his stay at Farnborough he promoted the development of methods for conducting aerodynamic research using rocket-propelled test vehicles, eventually co-operating with the Australian Weapons Research Establishment to extend the technique into the régime of hypersonic flight. Immediately before transfer to his present post he was head of the Projects Division of the Aerodynamics Department, and in this capacity responsible for the preliminary study of future military and civil aircraft.

Special Merit Promotions at the National Physical Laboratory:

Mr. H. H. Pearcey

It has recently been announced that Mr. H. H. Pearcey, of the Aerodynamics Division, National Physical Laboratory, has had a special merit promotion to deputy chief scientific officer. Mr. Pearcey is an internationally recognized authority in several branches of fluid dynamics, particularly the interaction between shock waves and boundary layers and the many intricate features of transonic, supersonic and separated flows. He has successfully used the results of his research in the progressive development of swept-wing aircraft for cruising at high subsonic, transonic and supersonic speeds by synthesizing methods for the design of the wing section and by evolving advanced section shapes. His 'peaky' type of aerofoil, with isentropic supersonic compressions, and the work that he initiated and supervised on aerofoils with thick trailing edges, including the use of automatic ventilation

to reduce the base drag, are well known. So also is his important discovery of the intrinsic connexion between the variation of static pressure at the trailing edge of a wing and the effects of shock-induced and other types of boundary-layer separation. His suggestion that this could be used to predict the threshold of aircraft buffeting has been widely exploited. Mr. Pearcey also made a classic investigation of methods for suppressing the separations that cause the buffeting and other undesirable aerodynamic characteristics. In particular, he demonstrated how the properties of vortex generators can be utilized in this respect and has been instrumental in applying them to numerous aircraft, thus effecting many significant improvements in aerodynamic behaviour and in safety at both high and low speeds. During the course of his work, Mr. Pearcey has made vital contributions to the development of experimental methods for research in high-speed flow and has played a leading part in planning, designing and commissioning the fine range of high-speed wind-tunnels now operating in the Aerodynamics Division of the National Physical Laboratory. Since 1958 he has been responsible for the High-speed Flow Group at the Laboratory; in 1963 he was awarded the Bronze Medal of the Royal Aeronautical Society, for his contributions to aerodynamics, and gained the Wolfe Award of the Department of Scientific and Industrial Research, for an outstanding contribution to the Department's research programme.

Dr. R. C. Lock

DR. R. C. LOCK, of the Aerodynamics Division, National Physical Laboratory, has been promoted to senior principal scientific officer (special merit). Dr. Lock is perhaps best known in aviation circles for his outstanding theoretical and experimental research that has produced aerodynamic design methods which render the concept of shock-free, low-drag flow—derived from the abstract infinite yawed wing—a reality for the finite-wing/fuselage combinations of practical aircraft, even for supersonic flight speeds. His papers on this subject are well established and extensively used by aircraft designers; one, on wing planform design, won the Royal Aeronautical Society's Edward Busk Memorial Prize for 1962. Dr. Lock is a leading figure in swept-wing research and plays a prominent part in several programmes in this and related fields that are co-ordinated between the National Physical Laboratory and other establishments in the United Kingdom, Europe and the Commonwealth. However, his reputation is more widely based than this. Already, before joining the Laboratory in 1954, he had had a brilliant career at Cambridge, and this had been interrupted at the end of the War by a brief but successful spell at the Royal Aircraft Establishment working on problems of aircraft design. At Cambridge he won the University Mayhew Prize for the best applied mathematics candidate in the Mathematics Tripos, Part III, and was awarded a research fellowship at Gonville and Caius College during the tenure of which he made important contributions in the fields of hydrodynamic stability and magnetohydrodynamics. At the National Physical Laboratory he first turned his attention to in-

volved problems of supersonic wing theory and wing/body interference, which led on to his work on swept wings, to his complementary experimental programme and to his active interest in the application of numerical methods and modern digital computers to outstanding problems in fluid dynamics. It is of considerable interest to note that Dr. Lock's work is in direct line of descent from the work that his father, the late C. N. H. Lock, pioneered at the National Physical Laboratory in the 1930's.

National Instrument Service in Britain

THE Science Research Council, in collaboration with the Ministry of Technology and the Office of Scientific and Technical Information, set up earlier this year a Panel under the chairmanship of Prof. G. Porter (University of Sheffield) to consider the feasibility and economics of a centralized national instrument service. A number of expensive, physicochemical instruments could provide a rapid service of routine measurements, on a repayment basis, for all scientists, such as those in Government, industrial and university laboratories. This service would enable physical-analytical techniques to be more widely available than at present and would thereby encourage the use of new instrumental techniques. Such a centralized arrangement would have additional advantages, particularly if it were associated with an interpretation service and data-store facilities. The Panel is hoping to find out whether such a service would be an effective means of meeting more economically the growing needs of research scientists for routine measurements on increasingly expensive research instruments. A description of some services which might be offered is being circulated, together with a brief questionnaire, to a cross-section of potential customers. The answers received will enable an assessment to be made of the need for services of this kind and of their economic viability. When this assessment has been thoroughly studied, the Panel will make recommendations to the Science Research Council regarding any future action.

Cambridge Engineering Freshmen

It is too early to know the state of this year's entry of students into the technological faculties of all universities and colleges of advanced technology, but a fact which should cheer industry is that at the University of Cambridge the number of freshmen entering the Engineering Department is 304, the highest in any year since the Mechanical Sciences Tripos was established in 1892. The exceptional quality of these men is indicated by the fact that 208 of them have been admitted to the fast stream which enables them to complete the course leading to the Mechanical Sciences Tripos Part I after two years of study instead of the normal three. As recently as 1960 the rate of freshmen entering the fast stream was only about one-third of the total intake.

I.C.S.U. Bulletin

The *I.C.S.U. Bulletin* (No. 4; July 1965), issued by the International Council of Scientific Unions, contains a brief account of the third meeting of the Executive Committee of the International Council of Scientific Unions, to which was presented a report on the Scientific Committee on Oceanic Research. There has been a steady increase in the activities of this Committee, which now has twenty-seven national adhering institutions. A report was also presented from the Scientific Committee on Antarctic Research, and a discussion on the work of this Committee directed attention to the near extinction of some species in Antarctica due to efficient and intensive fishing operations, and it was suggested that the restricted areas around Antarctica should be extended from 3 to 10 miles. The Executive Committee agreed that immediate action was necessary to prevent certain whales, particularly the blue whale, from becoming extinct. It also

discussed at length the increasing importance of solar terrestrial physics and the activities of the Inter-Union Commission on Solar Terrestrial Relations, its terms of reference and membership. A report was also presented from the Working Group on Relations with Developing Countries, and the suggestion was made that scientists from advanced countries should be encouraged to undertake missions in the developing countries. Scientists from the latter countries should be assisted to enable them to attend international meetings. The *Bulletin* also contains news from the scientific unions, including reports on: the work of the Committee on Atmospheric Sciences; the work of the Naples Zoological Station; the International Union of Biochemistry; and other reports from the Scientific Committee on Oceanic Research, the Committee on Space Research, the Federation of Astronomical and Geophysical Services, the Special Committee for the International Years of the Quiet Sun, and on the International Committee for Geophysics. There is also a list of publications, and the usual calendar of meetings for August 1965–January 1966.

International Paper Size

THE proposed change-over to the metric system in Britain will necessarily take a long time for full realization and it will pose many practical problems, both industrial and domestic. Not the least of these is the effect on paper sizes and printing, where tradition is likely to die very hard. If the proposed scheme of the metric-based 'International Paper Sizes' is adopted, it will completely revolutionize the present practice of the printing and publishing trades, with consequent repercussions in commerce, professional and private customs, particularly where books, pamphlets, display leaflets, stationery and envelopes are concerned, to mention only a few of the items involved. The keyword behind the conception of 'International Paper Sizes', as it is known, is simplification and rationalization. It means "... the introduction of a completely new range of paper sizes, from small to large, each based upon a metric measure and each related, in a logical sequence and proportion, to the rest of the range". One result, perhaps not unwelcome, will be the replacement of the time-honoured words 'quarto', 'crown', 'octavo', etc., by a numerical code, which will be universally understood. An impartial and non-technical exposition of the definitions, advantages and disadvantages of the 'International Paper Sizes' system has recently been published in the form of a booklet entitled *Paper at Work Number 4: International Paper Sizes* (A Series of Spicer Guides. Pp. 8. London: Spicers, Ltd., 1965). Included in this booklet is a full-sized A1 sheet (23.4 in. × 33.1 in., which is half the A0 size of 1 square metre. This A1 sheet is folded to demonstrate physically the full sizes of A2, A3, A4 and A5 and their relationship to each other. This example adequately illustrates the new code; the system is based on three series of sizes—all of the same proportion—designated A, B and C. The A series is perhaps the most widely used, for example, for stationery and general leaflet printing; the B series is intended primarily for larger printed items such as posters, wall charts, etc.; the C series, in conjunction with some of the B sizes, is intended for envelopes. In the ultimate adoption of this 'International Paper Size' system there are undoubtedly benefits of cost, convenience, international standardization and simplification. The disadvantages also have to be faced, but in the long run should not prove insuperable; for example, some printers' machinery may not be geared to handle 'International Paper Size' with optimum productivity; also office filing, filing equipment, addressing machines, etc. may not be suitable for dealing with 'International Paper Size' sizes; but these hazards will be overcome eventually and meanwhile everybody concerned has time for consideration and thoughtful reappraisal of the important

issues involved. Finally, the vital concern of all industry in Britain at the present time is export and it is here that 'International Paper Size' has come into its own. Twenty-six countries are using the system for commercial and technical paperwork; these include Austria, Belgium, Denmark, Finland, Germany, Holland, Italy, Norway, Portugal, Spain, Sweden and Switzerland.

Millboard Manufacture

THE main raw material in the manufacture of millboard is waste paper, and this, like many of the other commodities used in the process, has considerably increased in price since the end of 1964. Coupled with increased wages and overheads, and the fact that many overtime hours have had to be worked in the factory at Bourne End, Bucks., due to permanent under-staffing, the price structure of the products of Jackson's Millboard and Fibre Co., Ltd., has been correspondingly increased. These and some other interesting items are disclosed in the statement of the chairman (Mr. M. W. Jackson) at the seventy-fourth annual general meeting on September 29, 1965 (*Jackson's Millboard and Fibre Co., Ltd., Directors' Report and Accounts, 1965*. Pp. 12. London: Jackson's Millboard and Fibre Co., Ltd., 1965). The first fully automated intermittent board-making machine in Britain was installed in the Company's main factory in 1962. In this connexion, Mr. Jackson says: "In my report in September 1964 I referred to the purchase of the board making unit from Norway, and this installation is now on the point of completion. We have also modernized one of our existing board-making units at present concerned with the production of leatherboard, and this makes our second automatic machine. It is hoped that well before the end of the year we shall have three automatic board-making units in operation at Bourne End". These innovations should help considerably to mitigate price increases and expand the Company's export trade, an important item. But in spite of all efforts to improve efficiency, including expenditure on modern plant as described, "... the increases in operating costs over recent months are more than we are able to bear, if we are to show a reasonable return". Thus, even an advanced state of automation in manufacture, such as is in process of achievement in this factory, would not appear to be a panacea for all the economic ills in this industry at the present time. It can only be hoped that Mr. Jackson's somewhat gloomy foreboding will be dispelled by events this year in the shape of increased turnover and export business, especially in the Far East, where interesting results of overseas visits appear already to be bearing fruit.

Particle Size Measurement

A REPORT of a meeting, held in November 1963, at the British Ceramic Research Association, Stoke-on-Trent, to consider particle size measurement, has recently been published by the British Ceramic Society on behalf of the European Ceramic Association (Pp. 20. British Ceramic Society, Shelton House, Stoke-on-Trent, August 1965. 5s.). Measurement of particle size and interpretation of results to practical advantage are common problems in the ceramic and many other industries. Recent years have seen many improvements in traditional methods of measurement, such as using the microscope and the technique of sedimentation, but methods based on new principles have also appeared. It is pointed out, however, that unfortunately none of the latter has universal application, and so diversity of method increases. At the meeting four prepared contributions formed a basis for discussion: a review of the purpose of analysis and problems involved as seen by the British Ceramic Research Association; a report on a recent classification of methods undertaken by a sub-committee of the Society for Analytical Chemistry; an assessment of the Coulter

counter as a means of analysis of some ceramic materials; and an account of size analysis of clays within the sub-micron range. On the subject of appraisal of methods of particle size measurement now commonly publicized, some interesting results are revealed from replies to a questionnaire sent to industrial concerns, universities and colleges of technology. The questions concerned methods actually in use, type of material analysed, size-range, purpose of measurement (routine control, research, etc.). In so far as replies from 69 respondents may at this stage be considered representative, cautiously interpreted, they are certainly indicative, and fall into line with what might well be anticipated as the trend of things to-day. Summarily, sieving is the most frequently used single method; the Andreasen pipette method follows closely; sedimentation methods are generally popular; elutriation is relatively seldom used; gratitudes are frequently used, so also is the Coulter counter, while permeability methods receive a fair share of support. Of the 74 methods of particle size measurement in use and listed in the classification, 24 were not used by the respondents. Of the 69 replies received, 32 respondents used one method or another in routine control operations, 61 in research or development work. It is planned to organize comparative tests of some of the better-known methods on a large scale; possibly this may take the form of analysis by different laboratories of the same sample by the same method, or the analysis by the same laboratory of the same sample by different methods.

Surface Active Agents

SURFACE active agents are playing an increasingly important part in the manufacture of many diverse products in use in everyday life. These vary from materials such as oil paints and plastics, to duplicating inks and deodorants. These agents are incorporated in industrial and domestic preparations not only for their 'point of use' effect, for example, in shampoos, paint removers, etc., but also to facilitate manufacture, as in the case of emulsion paints, or to promote consistency in products such as cosmetic creams. The problem of determining the type of surface active agent present in a variety of different preparations is one constantly facing many analytical and industrial chemists, some of whom, by long experience, are experts in this field. Others, however, possibly the majority, have limited experience of these agents, and the apparatus requisite to their analysis. For the latter group, particularly, a most useful handbook has recently been published entitled *Surface Active Agents: their Extraction, Characterisation and Determination*, by Maurice Bell (Pp. 24. Leeds: Glovers (Chemicals), Ltd., 1965. 5s.). It is shown in this booklet that, in spite of the wide range of products of which surface active agents are important constituents, it is possible to divide such materials into a comparatively small number of groups: emulsions (oil-in-water or water-in-oil); aqueous based (that is, dissolved in water or mixtures of water and water-miscible solvents); non-aqueous based (dissolved or dispersed in oils, fats or organic solvents); and dry based (adsorbed on or admixed with powdered inorganic or organic materials, or similar in tableted or cake form). With this classification in mind, the various techniques and tests are considered under the appropriate headings: separation of the isolated surface active agents; characterization of the isolated surface active agents; quantitative examination of surface active agents; control of surface active agent concentration; chemical methods of control. The directions throughout, although to some extent summarized, are clear, concise and practical; if further detailed information on any procedure is required, then the list of references included will help. Domestic soap and detergent powders, washing-up liquids, and the like, are excluded from this booklet. They are the subject of special investigations and analytical schemes described

by other authors, to whom appropriate references are quoted. This little monograph is to be commended. It is the first of a series which it is the intention of the publishers to issue from time to time on various aspects of surface chemistry.

A Fresh Approach to the Problem of Allergy

G. B. West and J. M. Harris of the Department of Pharmacology, School of Pharmacy, University of London, have shown that rats secured from one Wistar albino colony are resistant to the first injection of dextran or egg-white, and that they fail to develop gross oedema of the extremities (the so-called anaphylactoid reaction) (*Ann. N.Y. Acad. Sci.*, 118, Article 8: *Pharmacogenetics—a Fresh Approach to the Problem of Allergy*. Pp. 439–452. New York: New York Academy of Sciences, 1964). Selective breeding experiments showed, first, that this non-reactivity is an autosomal recessive character, and secondly, that it is not linked with the colour genes for black or yellow. Pure stocks of non-reactor rats were established for both albino and non-albino strains, confirming that the anaphylactoid reaction is genetically controlled. Egg-white allergy in man is also partly inherited and also produces severe oedema of the exposed parts. It will be important, therefore, to determine the cause of non-reactivity of rats to egg-white and dextran, particularly as some genetical polymorphisms in man are known to produce biochemical differences.

Soil and Landscape at Archaeological Sites

It is not unusual for the pedologist to be concerned in the study of former occupation sites, and an interesting paper on the examination of soil profiles, and a suggested chronology of events in such a neighbourhood, has been prepared by P. H. Walker (*Records of the Australian Museum*, 26, No. 7; June 12, 1964: *Soil and Landscape History in the Vicinity of Archaeological Sites at Glen Davis, New South Wales*. Pp. 247–264+plates 25–27. Sydney: The Australian Museum, 1964. 6s.). The sites are in shelters formed from large erratic sandstone boulders on the lower slopes of the Capertree River Valley, Australia, where they are characterized by several hundred feet of intensively weathered coarse sandstone talus with narrow terraces. The debris on the upslope side of boulders reveals the past movement of the superficial deposits. The country rock is highly quartzose Triassic sandstone displaying strong current bedding. The deposits of the cave floors are relatively uniform and unstratified, and contain few rock fragments in comparison with the soil outside; but, according to modal particle size, are derived from the sandstone rock, are less sorted than the river deposits and have arisen from the deposition of coarse material in a sheltered position. Artefacts are found in the loose, sandy layers of the soil, which is unique in the locality. The soils inside and outside the caves are, however, to be regarded as minor surface disturbances of short duration in the development of the valley.

Gairdner Foundation Awards

THE 1965 Gairdner Foundation annual awards, valued at 5,000 dollars, have recently been awarded to: Dr. Charles P. LeBlond, head of the Department of Anatomy, McGill University, Montreal, for development of the technique of autoradiography; Dr. Jerome W. Conn, University Hospital, Ann Arbor, Michigan, for his pioneering work on the clinical significance of aldosterone; Dr. R. R. A. Coombs, Department of Pathology, University of Cambridge, for his work on antibody on the surface of red blood cells; Dr. Charles E. Dent, University College Hospital, London, for his work on paper chromatography leading to the discovery of diseases caused by imbalance of amino-acids; Dr. Daniel J. McCarty, Hahnemann Medical College and Hospital, Philadelphia, for his work on the causes of gout and rheumatoid arthritis; Sir Horace Smirk, University of Otago Medical School,

Dunedin, New Zealand, for his work on the application of nerve-blocking drugs in the treatment of high blood pressure. The Foundation was established in 1957 by J. A. Gairdner, the Toronto industrialist. Annual award of 5,000 dollars are bestowed on those who "have made contributions to the conquest of disease and the relief of human suffering".

David Anderson-Berry Prize, 1966

A DAVID ANDERSON-BERRY MEDAL, together with a sum of money, will be awarded by the Council of the Royal Society of Edinburgh during 1966, for recent work on the effects of X-rays and other forms of radiation on living tissues. Applications and proposals on behalf of others should be addressed to the General Secretary Royal Society of Edinburgh, 22–24 George Street, Edinburgh 2, from whom further information can be obtained. The closing date for applications will be March 31, 1966.

Announcements

PROF. O. V. S. HEATH, at present professor of horticulture in the University of Reading and honorary director of the Unit of Flower Crop Physiology of the Agricultural Research Council, has been appointed to fill a vacancy in the membership of the Agricultural Research Council, which has arisen on the retirement, after ten years' service, of Sir Hans Krebs.

THE sixth seminar on "Electrochemistry" will be held at the Central Electrochemical Research Institute, Karaikudi, during December 26–29. Further information can be obtained from Dr. K. S. Rajagopalan, Central Electrochemical Research Institute, Karaikudi 3, Madras State.

SEVERAL oceanographic meetings and conferences, sponsored by the Institute of Marine Science, will be held at Miami Beach during November 11–24. Further information can be obtained from the Institute of Marine Science, University of Miami, 1 Rickenbacker Causeway, Miami 49, Florida.

AN international conference on "Radiological Protection in the Industrial Use of Radioisotopes", organized by the Société Française de Radioprotection, will be held in Paris during December 13–15. Further information can be obtained from the Secretary General, Société Française de Radioprotection, Boîte Postale 3, Fontenay aux Roses, Seine.

THE winter meeting of the British Biophysical Society, on "The Conformation of Biological Macromolecules", will be held at Queen Elizabeth College, University of London, during December 20–22. Further information can be obtained from Prof. R. E. Burge, Department of Physics, Queen Elizabeth College, Campden Hill Road, London, W.8.

THE International Institute for Conservation is planning to hold a conference on "Chemicals in Museums: Quality, Care and Safe-handling" at the Institute of Archaeology, in the University of London, on January 27, 1966. The speakers invited to take part will include a factory inspector, the medical adviser to the Trades Union Congress, a representative from the firm of Hopkin and Williams, and a member of the Government Laboratory. Further information can be obtained from Miss Gedyne, Institute of Archaeology, 31 Gordon Street, London, W.1.

AN international conference on the "Lymphatic System", sponsored jointly by the Committee on Shock of the National Academy of Sciences–National Research Council and the Tulane University School of Medicine, will be held in New Orleans during December 12–14. Further information can be obtained from Prof. H. S. Mayerson, Department of Physiology, School of Medicine, Tulane University, New Orleans.

USE OF PIGS IN BIOMEDICAL RESEARCH

By DR. L. K. BUSTAD

Biology Department, Pacific Northwest Laboratory, Battelle Memorial Institute, Richland, Washington

AND

R. O. McCLELLAN

Medical Research Branch, Division of Biology and Medicine, U.S. Atomic Energy Commission, Washington, D.C.

THE first symposium devoted exclusively to the basis for and extent of utilization of pigs in biomedical research was held at the Pacific Northwest Laboratory, Richland, Washington, during July 19–21, under the sponsorship of the U.S. Atomic Energy Commission and the Battelle Memorial Institute (contract AT(45-1)1830). About 150 scientists from Canada, Denmark, France, Germany, Great Britain, Switzerland and the United States joined scientists of Battelle Memorial Institute's Pacific Northwest Laboratory (a U.S. Atomic Energy Commission facility formerly operated as the Hanford Laboratories by the General Electric Co.) for three days of formal presentations and panel discussions.

The symposium was divided into four general categories: (I) comparative anatomical and physiological characteristics; (II) biomedical applications of pigs and miniature pigs; (III) laboratory management practices; (IV) miniature pig development programmes. Session and panel chairmen were: D. L. Anderson, Division of Biology and Medicine, U.S. Atomic Energy Commission; T. J. Cunha, University of Florida; D. K. Detweiler, University of Pennsylvania; H. W. Dunne, Pennsylvania State University; D. C. England, Oregon State University; T. Gillman, Institute of Animal Physiology, Babraham, Cambridge; W. Montagna, Oregon Regional Primate Research Center; L. E. Mount, Institute of Animal Physiology, Babraham, Cambridge; and J. H. Rust, University of Chicago.

D. F. Cox, Iowa State University, reviewed pig genetics, pointing out that with the exception of information on the inheritance of blood antigens of pigs, knowledge of the genetics of inherited traits which are controlled by a few genetic factors is limited. He noted that domestic pigs provide some unique opportunities for research because of the vast array of genetic variation both between and within the various breeds.

Inheritance investigations described by J. Moustgaard and M. Hesselholt, Royal Veterinary and Agriculture College, Copenhagen, have shown that the presence or absence of antigenic factors on the surface of pig erythrocytes is genetically controlled by allele genes belonging to fourteen chromosomal loci. Blood group systems have been established and designated by letters A B C E F G H I J K L M N and O.

R. A. McFeely, University of Pennsylvania, presented recent work on pig cytogenetics. The pig appears particularly well suited for cytogenetic investigations because it has only 38 chromosomes, which can be readily paired and grouped in a manner not unlike human chromosomes. Of particular interest are studies in pigs with intersex conditions where chromosome analysis in several cases have shown that the role of the Y chromosome in the determination of sex may be somewhat different from that in man and the mouse.

D. Smidt *et al.*, University of Göttingen, reported on their investigations of reproduction using miniature pigs. They obtained fertilized ova by flushing oviducts and transferred the eggs from miniature sows to other miniature sows and reciprocally between miniature and

Landrace sows. The embryo implantation rate was 25 per cent, and 50 per cent of these were carried to term. The size of the sow influenced the birth weight and the proportions of the pigs. The weight differential persisted until they were about 6 weeks old.

Birthe Palludan, Royal Veterinary and Agricultural College, Copenhagen, presented an interesting, comprehensive review of teratological studies in pigs with avitaminosis-A. A number of malformations were observed, the most frequent being microphthalmia. No malformations were seen if vitamin A was administered to vitamin A-deficient sows before the 16th–17th day of gestation. Administration of large doses of vitamin A to pregnant sows caused eye anomalies and malformations of the heart similar to those caused by vitamin A deficiency. She also observed that thalidomide administered at high levels to pregnant pigs caused retarded development of the palate, heart, lungs, alimentary tract, and urogenital system.

L. E. Mount, Institute of Animal Physiology, Cambridge, described the patterns of heat production and heat loss in the new-born pig, relative to the pig's environment, and discussed some similarities to those observed in the human new-born.

S. L. Hansard, Louisiana State University, described extensive investigations of placental transfer and foetal utilization of absorbed minerals. He noted that absorbed minerals passed freely from dam to foetus at a rate which was inversely proportional to ionic size, but that the cations iron, calcium, phosphorus, and zinc traversed the placenta more rapidly than the anions iodine and phosphorus.

Several papers described work in the areas of dental and skeletal research. E. B. Jump and M. E. Weaver, University of Oregon Dental School, who pioneered the use of miniature pigs in dental research, described some advantages and limitations of this species. They noted that the pig masticates with both incision and trituration and is unique among the common laboratory animals in having a long period of deciduous and transitional dentition. This latter feature permits experimental investigations on many dental problems afflicting children. Their preliminary work demonstrates the suitability of miniature pigs for clinical experiments in restorative dentistry, orthodontics, periodontics, and the pathology and therapeutics of the tooth pulp. An interesting, but unexplained, difference they noted between man and pig was that the latter produces larger amounts of dental calculi without experiencing the periodontal pathology associated with dental calculus in man.

A paper by H. D. Dellmann and R. C. McClure, University of Missouri, described skull measurements to establish a co-ordinate system for stereotaxic placement in the brain of the pig. Their results suggest the possibility of developing a stereotaxic atlas for pigs even though breed and strain differences exist.

F. A. Spurrell, University of Minnesota, presented results obtained by him and his associates, W. J. L. Felts and L. A. Baudin, on the development of osteons in

pig and man, and the effect of dietary calcium restrictions. Cortical bone development in miniature pigs was compared and found similar to that in the standard domestic pig.

The structure of bones of starved pigs was evaluated by C. W. M. Pratt in a paper he presented with R. A. McCance, University of Cambridge. Newly weaned pigs were subjected to severe undernourishment for periods up to 1 year, maintaining their weight at 3–8 kg.

Their bones, although showing no specific pathology, were structurally distinctive, being unlike either normal growing bone or miniature mature bone. On the basis of calcium to collagen ratio, the bone appeared to be hypercalcified. Recovery of these undernourished animals occurred when they were allowed unlimited food. All bones ultimately reached close to their expected length, although mild deformities of the shaft appeared in some bones.

Only one paper on renal physiology was presented. In this paper, T. W. Nielsen with C. A. Maaske, University of Colorado, and N. H. Booth, Colorado State University, reported on their work on standard renal function tests performed on conscious unanaesthetized pigs. Endogenous creatinine, insulin, PAH, and osmotic clearances were determined. They reported that the pig has predominantly short-looped nephrons (97 per cent), compared with 86 per cent for man, whereas in the dog nearly 100 per cent of the nephrons are long. The ability of the pig to concentrate urine was also comparable to man. The pig, however, appeared to be insensitive to urea loading, and acetylation of the PAH in the pig probably compromises its use for clearance measurements using this material.

Several papers discussed gastrointestinal function and nutrition. D. F. Magee, University of Washington School of Medicine, described investigations of pancreatic secretion in pigs, which he found to have several advantages over dogs. He found that the volume of juice secreted is directly related to the hydrogen ion concentration in the duodenum of pH 7–1 and (unlike the dog) pepsin, oleic acid and olive oil all increased the output of amylase and lipase in the juice. Above pH 7, inhibition of secretion was noted. The pancreas seems to be involved in the regulation of duodenal pH on both sides of neutrality.

In a paper by T. W. Perry *et al.*, Purdue University, oesophago-gastric ulcers observed sporadically in pigs were described and were considered similar to those found in man. A high incidence of these ulcers could be produced by feeding corn, gelatinized corn, wheat, barley, or oats. Dietary additives such as α -tocopherol, menadione, vitamin A, antibiotics, copper, and methionine were without effect in preventing the oesophago-gastric ulcers.

W. G. Huber and R. F. Wallin, University of Illinois, analysed the gastric secretion from pigs bearing Heidenhain pouches or simple gastric fistulae. Differences were noted in pH, free acid, chloride, pepsin and histamine, between the two types of surgically prepared pigs; however, no significant difference was observed in total acid secretion. Difficulty was encountered in maintaining electrolyte balance in the pigs with the Heidenhain pouches.

Work on the sex-related differences in body composition in the pig and human infant was described by L. J. Filer *et al.*, University of Iowa. Filer noted that information on body composition of human infants is almost entirely restricted to that which may be accumulated by indirect methods of examination. He proposed that the growing pig be used as a model for comparisons to the human infant, permitting investigations on the influence of age, sex and diet on the rate of growth and body composition during infancy.

The application of pigs in investigations of severe protein malnutrition was discussed by W. G. Pond *et al.*, Cornell University. They found that when pigs were weaned at 3 weeks of age to dry, low-protein diets, bio-

chemical and anatomical changes occurred which resembled kwashiorkor in human infants. When a 3 per cent protein, low-fat diet was fed, the pigs remained active and alert and failed to develop the severe liver pathology and oedema seen in pigs fed a 3 per cent protein, high-fat diet.

B. C. Johnson, University of Illinois, also reported on the results of undernutrition of pigs, with emphasis on enzymatic and cardiovascular effects of starvation and re-feeding. Apparent irreversible damage was produced in myocardium as well as arteries and arterioles as a result of stresses of re-feeding following starvation. Johnson noted diastolic hypertension after only two starvation-re-feeding episodes.

E. R. Miller and D. E. Ullrey described cardiovascular effects in baby pigs with dietary deficiencies. Thiamine deficient pigs consistently exhibited bradycardia, sinus arrhythmia, and atrioventricular blocks. In recent years pigs have been increasingly used in cardiovascular research. In deference to this widespread interest, an evening panel was devoted entirely to cardiovascular research. D. K. Detweiler, University of Pennsylvania, who chaired this panel, reviewed the growing utilization of pigs in cardiovascular investigations, especially in North America and Germany. W. von Engelhardt, School of Veterinary Medicine, Hanover, presented a comprehensive review of pig cardiovascular physiology.

H. Luginbuhl, a Swiss scientist now at the University of Pennsylvania, discussed spontaneous atherosclerosis in pigs. Although it has been known for a decade that pigs develop lesions comparable to those of the pre-atheromatous phase in human atherosclerosis, Luginbuhl is the first to report on a large series of aged pigs (ranging from 8 to 14 years old). In these pigs, pre-atheromatous changes progressed to the formation of atheroma in the aorta, iliac, cerebral and coronary arteries of several animals. Luginbuhl identified all tissue elements constituting atheroma of man, and described for the first time the detection of complicated atherosclerotic lesions with ulceration and thrombus formation in pigs. Areas of cerebral occlusion were comparable to those in man.

H. C. Rowsell *et al.*, Ontario Veterinary College, reported on some of their investigations of the effects of dietary substances found in the diet of man on the development of atherosclerosis in pigs. Their work has shown that diets high in butter, egg yolk and lard plus cholesterol increased the amount of atherosclerosis and thrombosis in pigs. Rowsell *et al.* observed that, in endothelial preparations from pigs as young as 2 weeks of age, deposits rich in platelets occurred around vessel orifices and bifurcations in a topography and pattern similar to early atherosclerosis. Pigs were found to be ideally suited for the examination of the interactions of the vessel wall, the blood platelet, and blood coagulation.

Several papers were devoted to experiments involving heart surgery. C. A. Maaske, together with N. H. Booth and T. W. Nielsen, University of Colorado and Colorado State University, described experimentally induced cardiac failure in pigs. By partially occluding the main pulmonary artery of the pig, they produced a slow, progressive, right-sided, congestive heart failure accompanied by signs of clinical heart failure. They noted that induction of congestive heart failure in pigs was particularly significant, since cardiac failure was induced by a single surgical manoeuvre, while in dogs, multiple assaults or series of surgical manoeuvres are required to produce comparable results. At necropsy, grossly distended central veins, right atrial and ventricular dilatation and hypertrophy, hepatomegaly, and ascites were observed in affected animals.

G. D. Lumb, Warner-Lambert Research Institute, Canada, also reported on investigations of experimentally induced cardiac failure in pigs. Taking advantage of the similarity of the distribution of the coronary arteries of pig and man, he ligated the coronary branches supplying

the atrioventricular node and bundle of His, and then examined the degree of collateral circulation that ensued and the beneficial effects of medication.

D. C. Sawyer and H. L. Stone, U.S. Air Force School of Aerospace Medicine, reported on techniques and results of thoracic surgery for implantation of sensing devices for monitoring cardiac output and other parameters. They presented a coloured film on their surgical technique for implanting electromagnetic flow sensors placed around the ascending aorta. Implants remained functional more than 40 days. They reported values of 5.3 l./min for cardiac output, a stroke volume of 41 cm³/beat and a heart-rate of 124 beats/min in unanaesthetized pigs trained to recline quietly on a laboratory table. The major reason for their choice of miniature pigs over the dog for these investigations was the high incidence of aortic rupture in surgically prepared dogs.

In a more fundamental investigation, N. H. Booth with H. E. Bredeck and R. A. Herin, Colorado State University, reported on their work on the baro- and chemo-receptor reflex mechanism in pigs. H. Hoernicke, University of Hanover, closed the cardiovascular panel by reviewing the Berlin symposium on circulation in pigs. His review was largely concerned with *hertzsdod*, a cardiac disease in pigs of considerable economic importance in Germany. Differences in cardiovascular performance between domestic and wild pigs were also discussed. He noted that body-temperature loss appears to be an important factor in exercise tolerance by domestic pigs.

Normal haematological and biochemical parameters of miniature pigs were described by A. S. Tegeris *et al.*, Food and Drug Administration, and by R. O. McClellan *et al.*, Battelle-Northwest. Their papers provided extensive information on more than 30 parameters. Both papers emphasized the need for dynamic investigations in evaluating haematological and biochemical changes. McClellan emphasized the dynamic changes which appear to be age-related.

Another very interesting application of pigs is in certain immunological investigations, for which they seem uniquely suited. D. Segre, University of Illinois, stated that the immunological incompetence of colostrum-deprived baby pigs could be overcome by the administration of the antigen mixed with minute amounts of specific antibody or with large quantities of normal γ -globulin. By such investigations, support was generated for the natural selection theory of antibody formation, which holds that the antigen-antibody complex rather than the antigen alone constitutes the proper antigenic stimulus. The results presented by Y. B. Kim and by D. W. Watson differed somewhat from those of Segre. These workers, together with S. G. Bradley, University of Minnesota, found that "immunologic virgin" pigs appear to be immunologically competent, as manifested by their excellent response to antigenic stimuli—a single intraperitoneal injection of 10¹² particles of actinophage MSP-2. They found that germ-free, colostrum-deprived miniature piglets taken by hysterectomy 3–5 days before term were free of detectable immunoglobulins and antibodies if great care was exercised in preventing contamination of the new-born pig, with any foreign contaminant such as dam's blood. Of related interest also to immunologists was a paper by D. E. Ullrey, C. H. Long and E. R. Miller, Michigan State University, in which they investigated the absorption of intact proteins from the first milk of the mother for protection of the new-born pig. Colostrum-deprived pigs were used to establish that intact protein could be absorbed from the intestine after birth. This was done by feeding either a protein-free or protein-containing purified diet labelled with fluorescein isothiocyanate. One of their interests is to determine the mechanism of "gut closure", and in this regard they suggested that we may not have to wait very long for the clarification of this mechanism. It means for readily 'opening' and 'closing' the gut to γ -globulin-size

particles could be developed, it would represent a significant fundamental and applied technique for those interested in areas such as immunization and anaphylaxis.

Standard pigs are commonly afflicted with an arthritic condition that is of economic concern to pig producers. G. M. Neher and J. M. Carter, Purdue University, suggested that this naturally occurring arthritis of pigs bears many similarities to rheumatoid arthritis in man, although the aetiological agent is not common to both species. They observed that the disease could become active at any stage, and complete remissions were common in the early stages. Their work suggested that hypersensitivity is involved in the aetiology of the disease. R. W. Moore pointed out that at Texas A and M they have produced a mycoplasma arthritis in pigs which may be a superior model for rheumatoid arthritis in man.

F. D. Klopfer related the results of some of his investigations of visual learning in pigs at Washington State University. He found that unless special procedures are used in rearing very young pigs, they do not learn readily to solve visual discrimination problems for food reward. The effective procedures appear to be those preventing the strong development of position responses in feeding, so as to permit the development of visual discrimination while feeding. Using discrimination learning procedures, Klopfer found it was possible to demonstrate wave-length discrimination in these animals and to determine the photopic and scotopic visibility functions.

Pigs have been used quite extensively in radiobiological investigations; examples of present research in this area were reviewed in several papers. U.S. Naval Radiological Defense Laboratory scientists, in a paper presented by N. P. Page, described the recovery pattern of pigs given a large sub-lethal dose of X-irradiation. They found the acute $LD_{50/30}$ (mid-line air dose) of 8- to 9-month-old gilts was about 400 r. for 1 mVp. X-rays. Recovery from the effects of 238–265 r. exposures was estimated by re-determining the LD_{50} at various times after their initial exposure. The animals had recovered from 48 per cent of the initial injury by 3 days, and by 7 days the majority of animals appeared to have recovered completely. In fact, the data suggested that some of the animals had become radio-resistant. By 20 days the LD_{50} was about 170 per cent of the LD_{50} of the unconditioned animals.

In another paper on the effects of external whole-body radiation, D. G. Brown, University of Tennessee Agriculture Research Laboratory, reported on investigations of the late effects of pigs exposed to 15–700 rads of mixed neutron γ -radiation from a nuclear detonation 8 years ago. About 44 per cent of the irradiated pigs still survive compared with 69 per cent of the controls. The increased mortality in the irradiated pigs is attributed to gastrointestinal alteration and neoplasia.

R. O. McClellan reviewed the use of pigs in radionuclide toxicity investigations describing long-term examinations of the effects of daily ingestion of radiostrontium, investigations of the gastrointestinal absorption of plutonium and SNAF radionuclides, and metabolism and effects of plutonium deposited in the skin. He emphasized the importance of the size of the miniature pig, gastrointestinal tract and relatively long life-span as pertinent factors in favouring the use of the pig because of the importance of these criteria when results may be extrapolated to man. Of special interest was the reported high incidence of haematopoietic tissue neoplasms in miniature pigs ingesting large quantities of strontium-90.

For many years workers have regarded the skin of pigs as being very similar to human skin; it is only recently that careful, thorough, anatomical assessment has been accomplished by one of the outstanding authorities on skin, William Montagna. In a brief review of his work, Montagna stated that although pig skin shares some anatomical and histochemical features with that of man, it is distinctly different. The skin of both is characterized

by a sparse hair coat, a thick epidermis with a well-differentiated under-sculpture, a dermis which has a well-differentiated papillary body, and most noteworthy, a large elastic tissue content. In contrast to man, the pig dermis is poorly vascularized and the sebaceous glands contain much alkaline phosphatase. In view of his observations, Montagna recommended that caution should be exercised in suggesting that there is a strong resemblance between the two skins.

In his interesting paper on pig skin, G. D. Weinstein, University of Miami, found the kinetics of epidermal proliferation to be similar in man and pig. Using tritiated thymidine labelling, Weinstein showed that labelled cells in the epidermal basal layer had a transit time through the viable epidermis of 14 and 13 days in the pig and human epidermis, respectively. The total turn-over time of pig epidermis is about 30 days, while in human epidermis it is 27 or 28 days.

T. Gillman presented a film describing work on histogenesis of healing incised and excised wounds which he has performed with his associate, L. Ordman, at the Institute of Animal Physiology, Cambridge. Young pigs have been his principal subjects. Gillman stressed the indispensability of three-dimensional analysis of histogenesis. Sutures, he noted, evoked marked reactions especially in epidermis and skin appendages transected by the suture needle. Tape closure utilizing micropore (Minnesota Mining and Manufacturing Co.) was found highly effective in eliminating these complications and in permitting perfect healing without wound disruption. The results of this work demonstrate that widely accepted descriptions of healing cutaneous wounds are incorrect and therefore require revision.

Two papers described the results of radiation exposure of pig skin. In the first paper, J. O. Archambeau *et al.*, Brookhaven National Laboratory, reported on the use of pig skin for evaluating the effects of ionizing radiations. They concluded that the histology and radiation geometry of pig skin resembled the human sufficiently to warrant its use as an *in vivo* system for comparing effects of different types of ionizing radiations and extrapolating these results to man.

In a paper by the late L. A. George and L. K. Bustad, Battelle-Northwest, gross observations of early and late changes in pig, sheep and rabbit skin after acute exposures to phosphorus-32 or strontium-90 plaques were described. The pattern of early response observed in pigs resembled generally that described for man.

One day of the symposium was set aside for panel discussion of laboratory management and miniature pig development. L. E. Mount, Institute of Animal Physiology, Cambridge, was chairman of the panel on housing and handling. The members of this panel were: D. F. Cox, Iowa State University; A. Dettmers, University of Minnesota; F. L. Earl, Food and Drug Administration; R. L. Murphree, University of Tennessee (AEC); and R. O. McClellan, U.S. Atomic Energy Commission. The panel reviewed experimental pig units at their sites, and in this connexion made recommendations on housing, including floor space, air movement, temperature, feeding, water, and farrowing facilities, and on techniques in handling, including bleeding and anaesthesia.

S. G. Hastings, N. H. Booth and M. L. Hopwood, Colorado State University, submitted a paper on general anaesthesia for thoracic surgery procedures, and G. L. Waxler and C. K. Whitehair, Michigan State University, read a paper on techniques for using germ-free pigs in biomedical research. J. J. Landy, University of Miami, gave a brief report on his work with delivery and maintenance of germ-free pigs and the application of these procedures in human surgery.

Another panel discussed nutrition of pigs. The panel included the chairman, T. J. Cunha, University of Florida; A. Dettmers, University of Minnesota; L. K. Bustad for V. G. Horstman, Battelle-Northwest; L. J. Filer, Ross

Laboratories; E. G. Hill, University of Minnesota; C. K. Whitehair, Michigan State University; and J. P. Bowland, University of Alberta.

In addition, E. G. Hill submitted a paper on fatty-acid composition of miniature pig tissue lipids, and J. P. Bowland submitted a review of his extensive work on the composition of pig milk.

The third panel discussion was on disease and disease control. The chairman of the panel was H. W. Dunne, Pennsylvania State University. The panel members were: D. G. Brown, University of Tennessee (AEC); F. L. Earl, Food and Drug Administration; A. G. Edward, University of California, Davis; R. A. Griesemer, Ohio State University; R. O. McClellan, U.S. Atomic Energy Commission, for H. A. Ragan, of Battelle-Northwest; and M. J. Twiehaus, University of Nebraska. The panel reviewed the disease problems encountered and most likely to be encountered in experimental pig herds, and recommended an effective disease control programme for experimental pig herds and for the use of pigs in the laboratory.

D. C. England, Oregon State University, was the chairman of a panel on miniature pig development. The panel members were: W. E. Rempel, University of Minnesota; L. Welch, University of Nebraska; D. Smidt, Göttingen, Germany; J. C. Taylor, U.S. Department of Agriculture; P. Nizza, Fontenay-aux-Roses (Seine), France; and L. K. Bustad, Battelle-Northwest. The panel discussed the concept of miniature pig development and implementation of the concept, and defined essential features of existing herds.

In his introductory statement, D. C. England recalled that in 1949 the Hormel Institute of the University of Minnesota began the first project to develop a breed of miniature pigs specifically for use in biomedical research. Medical personnel of the Mayo Foundation gave added impetus, since it recognized the need for a convenient experimental animal that would better meet certain anatomical and physiological demands. The objectives of the University of Minnesota programme were to develop pigs with a mature size small enough to be easily handled and maintained, with normal physiological characteristics.

In the review of the various herds under development it was clear that one had an assortment of strains from which to choose. Several herds are white-skinned and have adult body-weights about the size of man.

An interesting recent introduction of the Labco pig, a gentle, sparsely haired pig obtained from Mexico by H. Quick, of Homewood, Illinois, into Hanford miniature pig was demonstrated. Many of the offspring were white and had sparse hair coats. The 'Labco' miniature and the 'Vitavet' lab. miniature developed by F. Conder, of Marion, Indiana, represent the only private development of miniature pigs which have come to our attention.

A promise of some very small stock from Nepal was reviewed by W. Rempel, University of Minnesota, who showed pictures of some pigs that weighed only about 10 lb. at one year of age. This is even smaller than the Vietnamese pigs which were imported by Haring *et al.* into Göttingen, Germany, and crossed with German 'Landrace' and 'Hormel' miniatures in their laboratory.

It appears that two classes of miniature pigs will be established on the basis of predicted need. Not only is there a real demand for pigs which have an adult weight less than 30 kg, but also for one that as an adult weighs about 70 kg, similar to the so-called standard man and to the weight of most of the miniature pigs now being used.

Collectively, the papers presented at the symposium reflect the present state of our knowledge on the applicability of pigs in biomedical research and establish the pig as an important and very promising experimental animal.

With the development of a standard 60-lb. pig which may well be available during the next decade, many pigs

will assume a major role in research laboratories. In fact, an appreciable increase in usage is predicted before this lower weight is realized.

Increased use of pigs and miniature pigs in the areas of genetics, nutrition, gastrointestinal and renal physiology,

immunology, toxicology, radiobiology, and fundamental and clinical cardiovascular physiology seems assured. Additional information is needed to provide a firm basis for a broader assessment of the future role of pigs in biomedical research.

NATURAL SELECTION AND TRANSMISSIBLE DISEASE

AN informal meeting on "Natural Selection and Transmissible Disease", arranged on behalf of the Human Adaptability Sub-Committee of the International Biological Programme (IBP), was held at the Ciba Foundation on July 21-22, 1965. In his introduction, Prof. J. S. Weiner said that there were now some thirty national IBP committees and it was envisaged that the programme would include both world-wide surveys on blood groups and other genetical traits and also more intensive multidisciplinary studies on selected populations. Genetical constitution in relation to disease had been adopted as an IBP topic, but so far there had been no discussion on the prospects of research or the methods to be used.

Speaking on "The Genetical Analysis of Disease Susceptibility", Prof. L. S. Penrose gave examples of inherited disease resistance in plants and animals, and pointed out that genetical analysis of this phenomenon in man was much more difficult. It was particularly difficult to disentangle the effects of inborn and acquired immunity and this made the interpretation of familial concentrations of such diseases as tuberculosis and acute rheumatism uncertain. Traditional beliefs about the differing disease susceptibility of racial groups might often be mistaken, and attempts to correlate body-build with disease susceptibility had not been convincing. Haldane initiated the modern approach in 1932, when he suggested that thalassaemia might protect against malaria, and Allison had provided evidence for this in the case of sickle-cell trait. In African peoples with high sickling rates, eradication of malaria could lead to a detectable fall of sickling frequency in three or four generations. Theoretical treatment of gene frequency dynamics was more complex for sex-linked genes and where several interacting alleles exist in the same population. He suggested that the effects of chromosomal abnormalities induced by viruses on susceptibility to other diseases might be worth investigating.

In the discussion, Prof. Penrose stressed the advantages of examining single-gene traits and questioned the value of twin-studies. Prof. Vogel thought that multifactorial characters should not be ignored and that useful data could be obtained from twins examined throughout their life-span. Dr. Kirk, Dr. Allison and Prof. Penrose discussed the interpretation of gene frequency differences between West Africans and American Negroes. Dr. Roberts suggested that genetical data might be collected on volunteers experimentally infected with the common cold. The relationship between susceptibility to disease and clinical severity was discussed by Sir Graham Wilson, Prof. Stuart-Harris, Dr. Omerod and Prof. Vogel.

Prof. C. H. Stuart-Harris spoke on the epidemiology of virus diseases. He said that their epidemiological behaviour was similar to that of bacterial diseases. Some, like poliomyelitis, were confined to man; others, like rabies, affected man by chance and did not spread; while others, which are spread by insect vectors, are maintained in the population by a cycle of transmission. Some virus diseases have been established for many centuries, and epidemics of these may be due to changes in virus virulence, host susceptibility or conditions influencing transmission. Viruses are well known to be plastic in the laboratory, but as yet it has not been proved that virulence changes underlie major epidemics. Viruses live in very close association with cells, and genetical variations in

the host tissues would be expected to be important in susceptibility. Mouse strains differing in resistance to certain viruses such as yellow-fever had been bred and inter-specific differences in susceptibility are well known. He gave examples of the varying relationship between attack-rates and severity of disease and the age of the subjects. He then discussed smallpox, influenza, yellow-fever and typhus. India and Pakistan are now hyper-endemic areas for smallpox, and mortalities might reach 40-50 per cent in some epidemics. Yellow-fever is endemic in West and Central Africa and heavy mortalities have occurred in recent epidemics in the Sudan and Abyssinia. Typhus, which is now endemic in the Middle East, North Africa, China and other regions, formerly caused heavy mortalities especially in persons more than fifty years of age. The influenza virus is very plastic and epidemics tend to occur when a new strain emerges. The work of McDonald and Zuckerman had shown that blood group O was more frequent among persons who had been infected with influenza A₂ virus, and unpublished work confirmed this. He thought that there was still scope for genetical investigations on populations to which certain viruses had not yet spread.

In the discussion, Prof. Barnicot asked for examples of non-immune populations which might be favourable for genetical investigations, and Prof. Stuart-Harris mentioned the measles epidemic in Greenland and polio epidemics among Eskimos. He said that Type I polio virus was absent in Tristan da Cunha before the exodus. In reply to Dr. Harrison, he said that little could be deduced about individual variations in susceptibility by measuring antibody titres. Dr. Roberts mentioned his own work on ABO blood groups in relation to *Rickettsia* infections in Nigeria, and Dr. Spicer spoke of his analysis of periodicity in deaths from respiratory diseases.

In his paper on "ABO Blood Groups and Infectious Diseases", Prof. F. Vogel said that in much of the earlier work on this topic the samples were too small, but relatively high B and AB frequencies had been found among patients with tertiary syphilis. His own work on ABO groups and smallpox had been stimulated by geographical correlations and by the claim, which was in dispute, that vaccinia virus contains A-like antigen. It was best, he thought, to seek correlations between blood group and clinical severity, and in India his team had found that scarring was more severe in subjects of groups A, B and AB or of groups A and AB than in those of group O. Clinically more severe cases among fresh smallpox cases in Pakistan were more frequent in groups A, B and also AB compared with O. Groups A and AB were in excess in a sample of post-vaccination encephalitis cases examined in Germany. Work in Austria suggested that infantile diarrhoea was more severe in group A children than in those of group O; German data for 1956 and 1960-63, which he himself had analysed, showed the same trend, but it was reversed in data for 1957-59. He felt that these various lines of work were sufficiently encouraging to deserve further attention.

In the discussion, Dr. Garhek reported a small series collected in a smallpox epidemic in Nigeria; no relation was found between ABO group and either the incidence or severity of disease. Dr. Allison expressed scepticism about the effect of ABO groups on smallpox infections. The possibility of collecting more data on tertiary syphilis, post-vaccination encephalitis and infantile diarrhoea was

discussed. Sir Graham Wilson pointed out the difficulties of diagnosis of post-vaccination encephalitis.

In a paper on the epidemiology of protozoal diseases, Mr. W. E. Ormerod said that disequilibrium between host and parasite could be adjusted by either of them becoming adapted by selection; owing to short generation times, adaptation of the parasite was likely to be more rapid. Some protozoa such as *Entamoeba coli* cause no disability in man; others, like *Plasmodium vivax*, cause illness; and some, such as *Trypanosoma rhodesiense*, are generally lethal. A benign parasite may be more harmful if other parasites are present. West Africans and American Negroes seem to have a solid immunity against *P. vivax* which is presumably genetical. This parasite may have been an important selective agent before equilibrium with man was achieved. Marked differences between certain cattle breeds in resistance to trypanosomiasis are known. This disease is enzootic in cattle but sporadic in man, and probably exerts little selective pressure on the latter. *Toxoplasma* is endemic in some human communities and may be a significant cause of abortion and still-birth. In general, if parasites can change rapidly, as can trypanosomes in contrast to plasmodia, host adaptation cannot proceed far in any direction. The highest selective pressures are likely to occur where a disease is holoendemic.

The epidemiology of toxoplasmosis and the immunity of Negroes to *P. vivax* were discussed. Dr. Allison considered that the latter phenomenon was genetical but not associated with haemoglobin variants or with G-6PD (glucose-6-phosphate dehydrogenase) deficiency.

Speaking on the epidemiology of bacterial diseases, Sir Graham Wilson said that the proportion of clinical, sub-clinical and latent infections and of uninfected people, both susceptible and immune, would depend on many factors. 98 per cent of people might catch a disease such as measles if it were introduced into a virgin population, whereas infectious anaemia of rats was widespread but latent. Probably most people are susceptible to plague and cholera, but these diseases do not occur to-day in Britain because conditions for transmission are unfavourable. Very little is known about genetical factors in disease resistance. Wide differences in the incidence of tuberculosis in troops of various nationalities in the First World War had been noted and in underdeveloped areas the disease assumes a rapidly progressive form when first introduced, but it is uncertain to what extent genetical differences are involved. Concordance work on twins is usually considered to show that genetical factors influence susceptibility to tuberculosis, but in a recent careful investigation Simonds attributed differences in twin responses mainly to environment. Certain cattle breeds and also mouse strains are known to differ widely in resistance to tuberculosis; in resistant mice there is better mobilization of mononuclear phagocytes, and strains resistant to *Salmonella typhimurium* have higher lymphocyte counts. Sir Graham Wilson thought that geneticists should direct the attention of epidemiologists to various simply inherited traits in the hope that they might be able to suggest possible connexions with disease resistance.

The role of nutrition in resistance to infections was discussed. Dr. Spicer said that both genetical and environmental factors were doubtless involved in susceptibility to tuberculosis. There had perhaps been a large epidemic of this disease reaching a peak in England in the nineteenth century. The interpretation of work on twins was further discussed and also the reasons why cholera tends to remain endemic in Bengal though occasionally breaking out elsewhere. Dr. Roberts had compared local variability in disease incidence in Nigeria with variability in blood groups and failed to find suggestive trends.

Dr. A. C. Allison spoke on "Genetical Components in Disease Resistance". He gave examples of single gene factors in bacteria conferring phage-resistance and in phages influencing infectivity. Resistance of insects to

insecticides had provided striking examples of evolutionary processes. In higher animals the picture is complicated by various immune responses. Evidence from work on bacteria, phage and on some mammals and birds indicated that genetical changes in cell surface components might affect susceptibility to attack by parasites. The susceptibility of certain mouse strains to polyoma and mouse hepatitis virus is greatly increased by thymectomy at birth. The Aleutian mink gene affects coat colour and also leucocyte morphology; the homozygotes are susceptible to a 'collagen disease' induced by a filterable organism. Dr. Allison summarized the work on sickle-cell trait and malaria and considered that the evidence for a protective effect was now quite impressive. Both in Central America and the Caribbean sickling rates tend to be low where selection due to malaria has been relaxed. Sickling rates in various regions correlate well with rates of G-6PD deficiency. He pointed out that ABO blood group heterozygotes such as AO and BO would presumably be handicapped in producing antibodies to two types of antigen and might therefore be at a selective disadvantage.

In the discussion, Prof. Vogel stressed that stable equilibrium due to heterosis might not be important in the case of ABO blood groups; one disease might push the frequency of a gene up and another push it down. Mechanisms other than heterosis for achieving equilibrium were mentioned by Prof. Penrose and Dr. Harrison. Experimental work on malarial infections in relation to sickling and G-6PD deficiency was discussed by Dr. Kirk and Dr. Allison. Dr. Edwards doubted whether protection against malaria by sickling should be regarded as an example of heterosis and whether this was the important mechanism in the case of blood group polymorphisms. Dr. Roberts mentioned his own work on both G-6PD deficiency and sickling in Nigeria.

Summarizing and commenting on the meeting, Prof. Barnicot said that many examples of disease resistance due to single genes in animals and plants had been cited, but the detailed mechanisms of gene action were generally not clear. Work on animals might suggest fruitful lines of research, but it showed only what might happen in man and not what does happen. On the whole, the meeting had emphasized the pitfalls more than the possibilities of work on genetical factors in disease resistance.

Lines of attack on this problem include (a) twin studies; (b) the study of disease incidence in families; (c) the genetical comparison of affected and control samples; (d) correlation of the geographical distributions of genes and diseases. Twin data are difficult to collect, and analysis of disease susceptibility cannot be pressed very far. Family studies are complicated by acquired immunity, and heterogeneity for age of subjects and infective dose. Comparison of affected and control populations may require very large samples to show convincing effects, though small selective pressures may be important in evolution. It may also be difficult to obtain a valid control sample. Many genes and many pathogens are known, and a blind search for associations is likely to be both fatiguing and futile. The examination of single gene traits clarifies the genetical aspect of a complex situation; in the case of multifactorial characters we may not know how much of the phenotypic variation is environmentally induced and disease resistance may depend on hidden effects of contributory genes rather than the visible phenotype. Geographical correlations may have been disturbed by relatively recent population movements and historical data on these may be meagre. In studying immigrant populations there are uncertainties about the exact origins of the migrants and the extent of intermixture in their new home. Genetical investigations of epidemics need special organization if good material is to be collected, since local conditions may not be favourable for scientific work.

A SIMPLE ASSESSMENT OF PARTITION DATA FOR CORRELATING STRUCTURE AND BIOLOGICAL ACTIVITY USING THIN-LAYER CHROMATOGRAPHY

By DR. C. B. C. BOYCE and DR. B. V. MILBORROW

'Shell' Research Ltd., Milstead Laboratory of Chemical Enzymology, Broad Oak Road, Sittingbourne, Kent

SINCE the work of Overton¹ and Meyer² the conditions for the penetration of compounds into cells and the structure of cell membranes have been the subject of continuous investigation. Collander³ has shown that the rate of migration of non-electrolytes into and out of the *Nitella* cell can be closely correlated with their partition coefficients between water and a number of organic solvents. Other factors such as molecular dimensions, hydration, adsorption and hydrogen bonding undoubtedly influence the rate of penetration, but the correlations observed for a number of biologically active compounds lead one to believe that partition coefficient is of overriding importance in controlling penetration of non-electrolytes into living cells⁴.

Hansch and Fujita⁵, and Fujita, Iwasa and Hansch⁶, have recently proposed a general mathematical relationship between the penetration of a molecule into cells and a substitution constant, π , which they support with excellent structure/activity correlations obtained with eight different classes of compounds, each assayed against a specific test organism. The constant π is based on partition coefficient and is defined by the free-energy relationship:

$$\pi = \log (\alpha_X/\alpha_H)$$

α_H = partition coefficient of a parent compound

α_X = partition coefficient of a derivative

The direct determination of partition coefficient is tedious and often presents practical difficulties, particularly when the compound is highly insoluble in either of the solvent phases. We have therefore turned to a simplified assessment of partition coefficient and its derivatives by exploiting the theoretical relationship between partition coefficient (α) and R_F value deduced by Martin⁷ for liquid-liquid partition chromatography:

$$\alpha = K (1/R_F - 1), \text{ where } K = \text{constant for the system.}$$

Bate-Smith and Westall⁸ introduced the term R_M , where $R_M = \log (1/R_F - 1)$. The change in the value of R_M for a substituent (ΔR_M) is a free energy-based constant identical with π used by Hansch. It is therefore possible in principle to correlate the penetration of substances with their R_M values. Preliminary results were encouraging, and we therefore investigated the system further and found that for this purpose the chromatographic method has many advantages over the conventional method of measuring partition coefficient.

We chose a series of *N-n*-alkyltritylamines for investigation (Table 1) because their observed molluscicidal activity can be attributed primarily to different rates of penetration to the site of action. An analysis of the toxicity of a range of trityl compounds⁹ has indicated that activity is associated with nucleophilic attack at the quaternary carbon atom of the trityl group:

Molluscicidal activity depends on the rate of penetration to the site of action and the facility with which the leaving group can be displaced when at that site. In the homologous series of *N-n*-alkyltritylamines the same toxicant is formed from all compounds and the relatively small differences in the nature of the leaving group have been found to make a negligible contribution to the observed activity. This can therefore be ascribed to different rates of penetration. The compounds were prepared by heating a solution of triphenylchloromethane (0.01 mole) in dry acetone (10 ml.) with the appropriate *n*-alkylamine (0.02 mole) for 1 h under reflux. The mixture was poured into water and the solid product was collected and recrystallized several times from ethanol, or, in the case of the hexyl-, heptyl- and octyl-derivatives, which were liquids, the compounds were isolated from the aqueous mixture by extraction with ether and were purified by chromatography on neutral alumina with hexane as eluent. Melting points and other data are given in Table 1.

§ Novel compound for which satisfactory analytical data were obtained.

Chromatography was carried out on glass plates (20 × 20 cm) coated with a 250 μ thick layer of 'Silica Gel G' (Merck). After drying at room temperature for 2 h and then at 105° for 10 min the plates were impregnated by allowing a 5 per cent solution of liquid paraffin BP in hexane (v/v) to run to the top of the plate; the solvent was then evaporated at 40°. The compounds (3 μ g/spot) were applied at 1.5 cm intervals along a line 2 cm from one edge of the plate so as to be 1 cm above the level of the developing solvent. In order to avoid any systematic error, compounds were applied to positions from a set of pre-determined random allocations, none being nearer than 2 cm to either margin. In addition, *N*-tritylmorpholine was run on all plates as a standard. The plates were developed by the ascending technique in a chromatography tank under conditions of equilibrium. The mobile phase, aqueous acetone saturated with stationary phase, was allowed to run for approximately 100 min when the solvent front had advanced 14 cm from the origin. The plates were then dried and the *N-n*-alkyltritylamines

Fig. 1. Relationship between R_M values and number of methylene carbon atoms in the n -alkyl chain of N - n -alkyltritylaminines in a series of acetone/water mixtures. With the exception of the Cl compound there is a linear relationship in all systems. Proportion of acetone (v/v) in the mobile phases: ●, 0.50; ▽, 0.56; ■, 0.67; ◇, 0.75; □, 0.82; ▲, 0.83; ○, 0.91

Fig. 2. Relationship between LD_{50} (\log_{10} molar concentration $\times 10^7$) and R_M when the proportion of acetone (v/v) in the immobile phase was 0.70

were detected by spraying with a solution of trichloroacetic acid (5 per cent w/v) in acetone. Yellow spots of the triphenylmethyl carbonium ion were produced after heating the plates at 100° for 5 min and, although these faded during the next 2–3 h as moisture was absorbed, they could be restored by repeating the detection procedure.

Estimates of LD_{50} (Table 1) were computed from dose-mortality data obtained with the snail *Australorbis glabratus*. Details of the procedure will be reported elsewhere⁹.

Since these compounds obey the Martin equation, that is, there is a linear relationship between R_M and the number of methylene carbon atoms in the side-chain (Fig. 1), we have related the biological activity of these compounds with their respective R_M values (Fig. 2). The quadratic relationship observed has been found in other chemical series and is attributed by Hansch and Fujita⁵ to an increase and decrease in the rate of penetration as the R_M values in a series change progressively and pass through an optimum.

The choice of chromatographic method is a matter of convenience; we have found no important differences between paper and thin-layer chromatography except that the latter is quicker and marginally more reproducible in our hands. Water is a constituent of the cell membrane and the protoplasm, so its use in one phase of the model system is obvious, but the lipoidal constitution of the cell membrane is unknown and the choice of hydrophobic phase must be somewhat arbitrary. From thermodynamic considerations, the nature of the non-aqueous phase should not affect the results qualitatively¹⁰ provided that there is no hydrogen bonding. Collander's results³ support this in that ether/water and olive oil/water partition coefficients are equally correlated with penetration into *Nilrella* cells.

Protein is absent from the aqueous and non-aqueous phases used for direct partition coefficient measurements. Therefore, the contribution of the proteinaceous material in a cell membrane is tacitly excluded from the model system. The justification for this is that the variation in penetration can be almost entirely accounted for by partition coefficient data. We were unable to detect any effect on the R_F values of the N - n -alkyltritylaminines when casein was incorporated into the silica gel support of the chromatogram (1 : 5 w/w) and we have therefore omitted protein from the chromatographic system for assessment of R_M values. We chose the reversed-phase system liquid paraffin/aqueous acetone with 'Silica Gel G' as support, although other materials, for example, alumina or Whatman No. 4 paper, impregnated with liquid paraffin were equally satisfactory and the R_F values were similar with all three types of support.

Using 'Silica Gel G' impregnated with liquid paraffin and 7 : 3 acetone/water (v/v before mixing) as mobile phase, it was possible to obtain R_F values for all members of the series of tritylaminines from methyl to octyl in the range of maximum accuracy (0.2–0.8) (ref. 11). However,

Fig. 3. The effect of solvent composition on the R_M of N - n -hexyltritylamine. Each point is the mean of at least ten determinations

in another class of biologically active compounds, the substituted benzonitriles¹², no single solvent system would give satisfactory R_F values for the most lipophilic and hydrophilic members which remained on, or ran close to, the origin and solvent front, respectively. We were able to overcome this difficulty and to extend the scope of the method by examining the R_F values of the tritylamines with mobile phases containing varying concentrations of acetone. Soczewinski and Wachtmeister¹³ have shown a linear relationship between R_M and solvent composition, provided that the solvent mixtures did not deviate markedly from ideal solutions. When the composition of the mobile phase was adjusted systematically, this relationship was confirmed for the tritylamines (Fig. 3). Given preliminary chromatographic data with a variable proportion of water in the mobile phase, it is possible to choose a solvent mixture which will give not only R_F values in the range of maximum accuracy for most of the compounds, but also maximum R_M increments (Fig. 1). The R_F values which fall outside these limits can be measured in a number of suitable mixtures and the R_M values for the primary system can then be obtained by extrapolation.

The conditions necessary for obtaining accurate and reproducible R_M values have been described in detail by Bate Smith and Westall⁸ for paper chromatography and have been reviewed by thin-layer chromatography, for example, by Stahl¹⁴ and by Truter¹⁵. The mean R_M values for the tritylamines, together with their respective inter-plate standard errors, are given in Table 1. The greatest source of error is the inter-plate variation, which is 6.5 times greater than the intra-plate variation, which was assessed by replication of a standard on each plate. Since there was no evidence that the inter-plate variation was dependent on the R_M value, the estimate of error could be pooled to give a standard error of 0.033 for a single determination and the standard error of the mean R_M value from nine determinations was 0.011. This is 1.2 per cent of the total range of R_M values examined. The mean standard error of the estimates of the log LD_{50} values expressed as a percentage of the range of these estimates is 2.6 per cent. The accuracy with which R_M can be determined is therefore adequate for structure/activity correlations because of the difficulty of assessing biological response with equal precision.

The measurement of the R_M values by reversed-phase chromatography has a number of advantages over the conventional partition measurements, the most important feature being that it is much quicker and less tedious because fewer manipulations are involved. Up to twenty

five compounds can be run simultaneously on one 40 cm × 20 cm thin-layer plate, so R_M values can be compared directly. The detection of spots by simple unspecific methods, for example, by iodine absorption or by the use of a fluorescent indicator, avoids the need for specific, quantitative analytical methods. As a corollary of this, it follows that impurities present will be detected or, alternatively, the material need not be pure provided that the salient spot can be identified. If necessary, the compounds can be extracted from thin-layer material.

The measurement of partition coefficients of sparingly water-soluble compounds demands a long period of equilibration to ensure thorough partitioning between the phases and then colloidal material has to be removed by centrifugation. After this there still remains the difficulty of measuring low concentrations of the solute. Reversed-phase paper or thin-layer chromatography in a range of solvent mixtures can give R_M values for any of these mixtures by extrapolation provided that the linear relationship between R_M and solvent composition is established. Very little material, often less than 1 µg, is required for detection. When the layer is overloaded the spots streak and such plates should be discarded, thus ensuring that the results will not be affected by the presence of colloidal material or by the degree of saturation of the phases by the substance under investigation. The chromatographic method provides a rapid reproducible means of obtaining quantitative partition data for many types of compounds that can be used to assess the roles of penetration and inherent effectiveness in the expression of biological activity. With the growing use of multiple regression techniques for the analysis of this kind of problem the importance of such data is likely to increase.

SPECTRAL DENSITY FUNCTIONS OF HYDROMAGNETIC EMISSIONS AT HIGH LATITUDE

By DR. ALV EGELAND

Norwegian Institute of Cosmic Physics, Blindern, Oslo

IN this article the regular emissions in the frequency range 0.5–5 c/s are considered. Interest in them has increased considerably during the past five years, but the approach to the problem adopted here is somewhat different from that employed hitherto by other workers. The nomenclature for this type of oscillation is rather complex. In 1964 the IAGA committee (cf. Jacobs *et al.*¹) recommended that the term Pc 1 should be used for regular oscillations between 0.2 and 5 c/s, but many workers have also referred to these signals as hydromagnetic emissions, pearl pulsations, 'type A' oscillations, etc. (compare, for example, Troitskaya², Campbell³, Gendrin and Stéfant⁴, and Topley⁵). In what follows the term 'hydromagnetic

emission' (HM) will be used to describe the regular oscillations in this ultra-low-frequency range.

The principal detection systems used normally comprise iron-core loops (or air-core), low-noise amplifiers (between 0.1 and say, 10 c/s), chart and/or magnetic tape records. The use of tape makes possible careful analysis after the phenomenon has been observed. The HM emission data obtained have normally been presented in one or both of the following two types of displays: (a) amplitude against time, and (b) frequency against time (sonagrams). Both these methods of presenting data offer much valuable information concerning the micro-pulsations

Fig. 1. Spectral density function for the Tromsø hydromagnetic emission record on December 9, 1964. *a*, Record between 2147 and 2149 M.E.T.; *b*, record between 2151 and 2153 M.E.T.

However, if we take the resolution time on the sonagrams this is normally no better than the order of 10–30 sec, and the signal amplitude of sonagrams can only be read off with an accuracy of about 20–30 per cent. This means that the bandwidths as well as the mid-band frequency of ultra-low frequency emissions cannot be determined accurately. Concerning the amplitude against time display, Pope⁶ has shown that these records must be used very cautiously when more than one emission frequency occurs, as the amplitude is strongly dependent on both the number and amplitude of beating frequencies in the emissions.

I therefore feel that if one could find a simple and accurate method of evaluating spectral density functions of HM emissions, it would be of great additional value for the two types of data presentation mentioned here; especially where bandwidths, centre-frequency and power density are concerned. Power spectra can, of course, be evaluated from amplitude-time displays, but the normal methods for reduction and computation of power spectra are time-consuming and not favourable for statistical analysis (cf. Vozoff *et al.*⁷).

This communication describes an accurate and rather simple method for power spectral analysis of micropulsations, and demonstrates two examples of HM emissions recorded in this way. The measurements were started at the Auroral Observatory at Tromsø ($\Phi = 70^\circ \text{ N.}$, $\lambda = 19^\circ \text{ E.}$) last autumn. The rapid geomagnetic fluctuations were received on an air-core loop antenna, with an effective absorbing area of approximately 3,000 m² and with the axis located in the magnetic N.–S. direction. A d.c. preamplifier, with maximum gain of approximately 100 dB for 1 μV input, was used. With a frequency-modulated adapter (cf. Mohus⁸) connected to a magnetic tape-recorder,

it is possible to record (with a tape speed of 7.5 in./sec) signals between d.c. and approximately 200 c/s. All the instruments were transistorized and battery-powered.

The tape-records are analysed on 'ISAC', a statistical analogue computer, designed and built at the Automatic Control Laboratory of the Norwegian Institute of Technology. ISAC computes correlation functions, power spectra and first-order distribution functions for signals in the frequency range 0–200 c/s. All computations, which are performed at high speed, are done automatically and the results are plotted direct by an *xy*-pen recorder. The resolution in frequency and power is high (see below). Frequency- and amplitude-calibrations are automatically carried out. ISAC weighs approximately 40 kg and may easily be carried around. (For further details concerning ISAC, compare, for example, Balchen and Blandhol⁹.)

Two samples of spectral density function of HM emissions evaluated by this method shown in Fig. 1*a* and *b*. The calculation and plotting of each power spectrum take about 8 min. No attempts at smoothing

the curve have been made. Fig. 1*a* displays the spectrum recorded on December 9, 1964, between 2147 and 2149 M.E.T., while Fig. 1*b* illustrates the spectral density of HM emission recorded 2 min later the same night: also in this case only 2 min of actual recording on the tape has been used in the analyses. The frequency accuracy is better than 0.1 c/s for both spectra.

As easily seen from the curves in Fig. 1, three dominant narrow bands are observed. Mid-band frequency as well as the bandwidth of the HM emissions can be measured very accurately direct from the curves. The centre frequency of these bands in Fig. 1*a* is 0.95, 1.7 and 2.95 c/s, while the corresponding figures for Fig. 1*b* differ by less than 0.2 c/s. The frequency widths (half-widths) for these three pronounced bands shown are 0.18, 0.32 and 0.1 c/s measured from the origin, while the corresponding bandwidths in Fig. 1*b* are 0.4, 0.13 and 0.2 c/s. The ratio between the band-width and the centre frequency ($\Delta f/f$) varies from 0.4 to about 0.03; thus the pulsations of HM emissions are normally confined to a very narrow frequency-band.

On first viewing these emission curves, it may look as if the second and third peak (measured from the origin) are the second and third harmonics of the first band, but the figures given here show that this is not the case. However, it can be objected that a rather large uncertainty exists in defining mean periods and bandwidths when such relatively short intervals of data are used. On the other hand, as these two curves are almost identical (except for the fine structure), both the mid-band frequency and the bandwidths of this HM emission should be significant.

It is difficult to devise accurate calibration for measurements of this type and, so far as I know, very little has been

Fig. 2. Amplitude-time display. Record on December 9, 1964. upper, between 2147.30 and 2147.47 M.E.T.; lower, between 2152.05 and 2152.22 M.E.T.

written concerning signal strength of ultra-low-frequency emission. Unfortunately, no satisfactory calibration was carried out during December 9. But from later measurements it seems possible to conclude that the peaks in the spectra shown in Fig. 1 correspond to a variation in the magnetic field of the order of a few $\text{mG s}^{-1/2}$. This implies that the ultra-low-frequency emissions contain rather low energy compared with micropulsations in the frequency range between, say, 0.1 and 0.001 c/s. But, on the other hand, the amplitude resolution with this type of data presentation (cf. Figs. 1a and b) is very high.

That fine structure exists (superimposed on the regular band emission) is seen in the spectral density functions. However, detailed studies of fine structure of HM emissions can be made more directly and simply from frequency-versus-time displays (sonagrams).

With the other methods of presenting data that have been mentioned, it is very difficult to determine, with extreme accuracy, bandwidths and mean periods. This is especially true for the amplitude-time display. To illustrate this better, a small part of the amplitude-versus-time records obtained during the same time interval as the magnetic tape data used for the plotting of two power spectra discussed here, are shown in Fig. 2. The wave-form display varies more or less symmetrically about a base line but, as is easily seen, the modulation pattern is rather irregular, and they scarcely seem to exhibit a characteristic modulation frequency. Therefore, an interpretation of the spectrum based, for example, on the peak-to-peak interval can be completely misleading. It is also

impossible to arrive at the number of emission bands directly from such wave-form display.

Furthermore, it should be pointed out that the two spectral density functions of HM emissions, described here, were recorded during magnetically quiet conditions and no riometer absorption occurred during this time. Also, during the 12 h immediately before and after this time of observation, scarcely any magnetic- and/or riometer-deflexions could be seen on the diagrams.

Many other power spectra, with quite different shapes, have been obtained. These results together with theoretical considerations will be discussed in a later report.

This work was supported by the Cambridge Research Laboratories, OAR, through the European Office, Aerospace Research, U.S. Air Force, contract AF 61 (052)-811. I thank Mr. I. Mohus of the Norwegian Institute of Technology for help with the power spectra analysis.

COINCIDENCE OF MAGNETIC DISTURBANCES WITH LOCAL EARTHQUAKES RECORDED FROM THE ETHIOPIAN RIFT SYSTEM

By PROF. PIERRE GOUIN

Geophysical Observatory, Haile Sellassie I University, Addis Ababa, Ethiopia

LABORATORY experiments¹⁻⁷ have been carried out to investigate the behaviour of rock magnetic susceptibility under conditions thought to approach those at focal depth prior to, or at the moment of, an earthquake: slow stress accumulation, sudden shear stress release, various Earth magnetic field intensities and orientations using different rock types, etc., in order to foresee what kind of magnetic anomalies might possibly be expected in the local magnetic field when an earthquake occurs.

Some authors have even expressed the opinion that some magnetic anomalies prior to a seismic event could even be used as a method for predicting earthquakes^{7,8}.

In general, however, authors do not agree^{4,6,7} on the total validity of the laboratory experiments on the grounds that they either do not reproduce the exact conditions prevailing at the seismic focal points, or simply because earthquake mechanism is not yet completely understood⁷ and varies according to local geological or tectonic conditions. I presume that the study of well-controlled field data may provide a more solid basis to the discussion of the problem. What, in fact, do geophysical stations equipped with both magnetic and seismic recorders register prior to or during a seismic event of a given magnitude (M) occurring at limited epicentral distance?

The Geophysical Observatory at Addis Ababa (09° 02' N., 38° 46' E.) is in a favourable position to answer such a question. About 175-200 km north-north-east from the station, on the western escarpment of Afar, lies the very seismically active region of Kara-Kore, from where more than 3,000 shocks were registered during the summer of 1961; two of these shocks were of $M \geq 6.2$. At a similar distance to the south-south-west on the floor of the Main

Ethiopian Rift is the dormant volcano Chubbi; this region is less active than Kara-Kore, but nevertheless experienced in 1960 an earthquake of $M = 6.3$. Thirdly, 500-600 km to the north-east of Addis Ababa is situated the seismically active region of the Gulf of Tadjura.

Since its opening, the magnetic station at Addis Ababa has been equipped with three standard Ruska variographs (H , D and Z) operating at sensitivities of about 3 γ/mm , with a time base of 20 mm/h. Prior to November 1962, the S_0 for D was 10 γ/mm .

In February 1965, two high-sensitivity rapid-run Selzer Fluxgate H and D magnetometers (supplied through the courtesy of the Institut de Physique du Globe, Paris) were put into operation with galvanometer periods of 0.5 and 4.0 sec, and with over-all sensitivities ranging from 0.02 to 0.002 γ/mm adjusted according to the level of sferics. These flux-gate magnetometers are insensitive to seismic noise and long-period magnetic variations.

In order to detect any magnetic effects related to local earthquakes, all the magnetograms since March 1959 (date of opening of the AAE seismic station) were attentively examined for unusual magnetic disturbances prior to, simultaneous with, or following a local earthquake of magnitude $M \geq 5.0$ (Eichter intensity scale). Since the Ruska H and D variometers are of the pendulum type, they are sensitive to earth tremors and, under the violence of local shocks of the aforementioned magnitude, the photographic traces disappear for periods of time often as long as 9-10 min. It should be noted, therefore, that the magnetic disturbances discussed here and indicated as coinciding with Earth tremors may have taken place either suddenly, or gradually during this 'black-out' period.

Table 1

Seismic data					Magnetic data			
No.	Date	Origin time L.M.T.	Epicentral distance	M	ΔH	ΔD (?)	ΔZ	Observations
1	1958, May 25	02:54	635 km	5.5	0	—	—	
2	1958, May 25	05:54	635	5.0	R	R	R	
3	1960, July 14	21:40	240	6.3	R	0	—	
4	1960, Aug. 8	15:28	715	5.4	0	0	0	
5	1961, Mar. 11	11:41	545	5.9	-15	0	0	ΔH may be due to normal magnetic activity
6	1961, May 29	07:60	205	5.0	-5	0	—	$\Delta H = 4\gamma$ about 36 min ahead (?)
7	1961, May 29	13:52	150	5.5	-20	0	0	Small pip at 13:30
8	1961, May 29	22:24	200	5.0	0	0	0	H-trace at night-level
9	1961, May 29	22:26	210	5.0	?	?	?	Effect covered by previous shock
10	1961, May 30	16:11	220	?	-1	0	0	
11	1961, June 2	02:29	210	6.4	-16	0	0	H-trace above night-level due to a magnetic bay
12	1961, June 2	07:51	195	6.2	-4	0	0	
13	1961, June 2	08:22	200	?	-12	0	0	
14	1961, June 2	08:45	215	5.8	0	0	0	
15	1961, June 2	10:03	175	5.5	0	0	0	Magnetic activity: $k=5$, $C_1=1.3$
16	1961, June 3	18:23	205	5.8	?	?	?	Too many shocks to detect any reliable ΔH
17	1961, June 14	23:32	210	5.7	0	0	—	$\Delta H = 2-3\gamma$ 42 min ahead (?)
18	1962, Nov. 11	18:15	915	5.6	0	—	—	H-trace at night-level
19	1963, Oct. 5	17:58	530	5.3	0	0	—	H-trace at night-level
20	1964, July 3	22:19	230	5.0	0	0	—	H-trace at night-level

R, Record missing. —, Event not recorded on that component.

Table 1 sums up the observations on Ruska magnetograms for local earthquakes of $M \geq 5.0$ at the moment of the seismic registration. On these magnetograms, no abnormal magnetic disturbances have been detected either prior or subsequent to the Earth tremors. It must be emphasized that the ΔH , ΔD and ΔZ values indicated in Table 1 do not refer to the amplitude of the pendulum oscillations, but to a sudden permanent change in the intensity of the magnetic field. The station being situated at the magnetic equator, $H \approx F$.

From Table 1, it appears that at the moment of a local earthquake:

(1) No permanent change in declination (D) or in the intensity of the magnetic vertical component (Z) has yet been observed.

(2) Magnetic disturbances prior to the seismic events listed as Nos. 6, 7 and 17 could only questionably be related to these events and are in no way outstanding.

(3) Permanent changes in the intensity of the magnetic field (restoration of the field to its normal value) are observed at the time of the registration of local earthquakes and are always negative.

Fig. 1. Ruska standard magnetogram of May 29, 1961, showing the sudden decrease in the value of H at the moment of local earthquake No. 7 in Table 1. The tremors following that seismic event show no apparent change with intensity of the field

(4) Neglecting a possible effect of focal depth for tremors of approximately equal epicentral distances and magnitudes, the negative magnetic disturbances (ΔH) show a certain tendency to be enhanced during day-time, when the H (or F) trace is above night-time level (compare events Nos. 6 and 13 with Nos. 8, 17 and 20). There are, however, three apparent exceptions to this tendency.

(a) Earthquake No. 11 happened at night (L.M.T. 02:29) but shows a $\Delta H = -16\gamma$. The occurrence of this earthquake coincided with a magnetic bay when the H -trace was above the normal night-level. The decrease in intensity of the magnetic field by 16γ may either be due to the earthquake or may simply mark the end of the magnetic bay.

(b) Earthquakes Nos. 14 and 15 happened in the morning when the H -trace was well above night-level; the seismic magnitudes were respectively 5.8 and 5.5 and epicentral distances 215 and 175 km, but no magnetic disturbances were registered. Observations show, however, that this absence of magnetic disturbances prevails during a swarm of tremors. Earthquakes Nos. 14 and 15 were preceded by two shocks which released -4 and -12γ , respectively, within 56 min. Many other similar examples could be given. In a swarm of quakes, when tremors follow one another at short intervals, the total piezo-magnetic energy is released during the first shocks, and if a new build-up of piezo-magnetic energy does occur in such a short period of time (a few minutes) its intensity is too weak to be recorded 200 km away.

(5) The theoretical rate-of-change in the intensity of the Earth magnetic field during the hours or days preceding a major seismic event cannot be expected to be observed at magnetic stations under the influence of the equatorial electrojet; it would be hidden in the unpredictable variability of the daily Sq variation.

A question arises: Could the displacement of the H -trace on the Addis Ababa records, interpreted as a variation of the magnetic field at the moment of a local earthquake, be mistaken for seismically induced physical displacements of the working parts of the H -variometer? Such a possibility is very doubtful because:

(a) The variometers at the station are solidly cemented to their pier and their base can in no way be moved. Had they been moved under the seismic shock the baseline traces also would have been displaced, since the mirrors for these are attached to the base of the instruments.

(b) The mechanical effects would therefore be restricted to the pendulum, which is free to oscillate within the limits of its damping cup. One does not easily understand why, in a series of earthquakes of equivalent magnitudes and epicentral distances, a few shocks happening when

Fig. 2. Flux-gate record of April 14, 1965, showing possible magnetic effects of earthquake No. 6 in Table 2 (the record has been retraced by hand owing to the faintness of the trace)

the H -trace is above night-level would cause a physical disturbance on the H -pendulum when all the other shocks occurring at night-level hours did not produce any such physical disturbances (Table 1).

(c) The instruments have been submitted to a mechanical vibration test (because of the solidity of the pier, the seismic oscillations could not be exactly reproduced) and no permanent change in the position of the H -trace has been noticed. I think that seismic shocks as mentioned in (b) are still the best test.

Moore⁹ reported an astonishingly sudden increase of 100γ in the intensity of the total field (F) recorded on a flux-gate magnetometer at Kodiak, 66 min before the Alaska earthquake of March 27, 1964. Kodiak was 440 km away from the epicentre. Unfortunately, Moore's comments are based on a single observation.

Breiner¹⁰ mentions repeated events recorded just prior to local earthquakes, but although his records (*op. cit.* Fig. 2) show a positive disturbance 10 min before the seismic event studied, he refrains from commenting on this magnetic disturbance until more evidence becomes available.

The flux-gate magnetic records from Addis Ababa have been examined in correlation with local earthquakes, some of which are listed in Table 2. I admit that the choice of seismic events in Table 2 is not ideal, owing to generally low magnitudes and to epicentral distances higher than 300 km, but this cannot be remedied until more and bigger local earthquakes are experienced at Addis Ababa.

Table 2

No.	Date	iP (L.M.T.)	d (km)	M	Magnetic observations
1	1965, April 13	05:36:28	850	5.1	No magnetic disturbance
2	" "	23:26:58	300	2.7	" "
3	1965, April 14	04:05:08	320	2.5	" "
4	" "	06:13:05	320	3.1	" "
5	" "	07:13:08	350	3.7	Small + pips at 06:55 35 and 07:17:10
6	" "	10:53:11	350	4.3	See Fig. and comments below

Of the six events listed in Table 2, only the last one ($d = 350$ km, $M = 4.3$) showed any magnetic disturbances (Fig. 2) which could be termed unusual, but these certainly would not be differentiated from normal magnetic pulsations if it were not for the knowledge that a local earthquake had, in fact, occurred and that therefore seismo-magnetic effects might be expected.

Fig. 2 shows a part of the flux-gate magnetic H -trace recording for July 14. Both the origin time and iP -phase recorded time are indicated. The very small pips on the magnetic trace are lightning effects, well recorded on the D -trace. Prior to iP (10:53:11), no unusual magnetic

disturbance could be detected. At 10:56, a large isolated sinusoidal pulsation (x) occurred, but this is nothing unusual on the flux-gate records. Later, at 11:11 and 11:14.5, two similar very sharp and quite unusual positive pulses (A and B) appeared at the end of 30-sec abrupt increases of the magnetic field. Note that these disturbances do not appear on the D -trace.

The last two negative disturbances marked A and B are presumed to be seismo-magnetic, but further observations are necessary before a cause-to-effect relation could be affirmed.

In conclusion, from the examination of the standard magnetograms at Addis Ababa, up to now at least, it appears that:

(a) No disturbance in the local magnetic field has been observed either prior to or following a local seismic event originating in the Ethiopian Rift system.

(b) Negative stepped decreases in the intensity of the total magnetic field ($E \approx F$ at Addis Ababa) have been observed coinciding in time with local Earth tremors. (Nagata and Kinoshita⁶ would have expected $a + \Delta H$.) The amplitude of the decrease ΔF seems proportional to the magnitude of the earthquake (therefore to the stress accumulated), to its epicentral distance from the station, and most probably to the amplitude of the positive daily variation (S) of the magnetic field above the mean night level. Such a decrease in the intensity of F has also been observed by Breiner in Nevada¹⁰.

(c) The seismo-magnetic effects produced no deviation in magnetic declination such as Miyakoshi¹¹ has observed in Japan.

Unexplained phenomena have also been noted on the high-sensitivity short-period flux-gate recording either before or following local seismic events. Their polarity seems to be positive while the permanent magnetic effects on standard magnetograms have been observed to be negative. However, the time of their appearance in relation to either the origin time of the earthquake, its iP recorded time at the station or its epicentral distance, is so inconsistent that much more evidence is needed before any conclusion could be drawn.

RELATIVE SIMILARITIES IN ONE DIMENSION

By PROF. J. W. CARMICHAEL, PROF. R. S. JULIUS and DR P. M. D. MARTIN

Mold Herbarium and Culture Collection, and Departments of Computing Science and Bacteriology, University of Alberta, Edmonton

PERCEPTION, in man, is the act of deriving some meaning or message from signals transmitted to the brain from the sense organs. It consists of detection, in a set of simultaneous or sequential signals, of sets of interrelations among the signals, which we may call 'patterns'. The human brain, then, must have some mechanism for detecting patterns in signals and also for comparing recently received patterns with previously received ones. We do not know what this mechanism is, but when a pattern is recognized as a familiar one, we call the process identification. When a pattern is recognized as novel, the process is classification, or concept formation, because in the recognition of novelty we have added a new pattern to our repertory. In other words, we have added a new concept to our view of reality, or we have enlarged our perceptual sorting system for deriving meaning from signal input, or we have added a new class to our classification of all things.

This process begins at, or before, birth, and continues day by day and minute by minute. The result is a mapping, in the brain, of what we conceive of as reality. Reality for the individual can only be his map of what the world is like in relation to the signals he receives. 'Reality' in the sense of 'what the world is like in relation to man collectively' is the object of scientific investigation. We can say that whenever concepts about reality lead to reliable predictions, and hence useful responses, the concepts are valid ones. When they do not lead to reliable predictions or useful responses, the concepts are 'wrong'. Validity of concepts can only be judged on their utility, even though we may hope that the concepts of science form an undistorted mapping of the physical universe.

Of course, this process of concept formation, or development of pattern sorting systems, soon becomes complex. Without receiving new signals, we can detect patterns of patterns when we have a large store of them in our repertory (and perhaps even conceive of patterns not implicit in our repertory). This process we might call abstract conceptualization.

In the classification of bacteria, as in many problems in psychology, the attributes available for classification are largely non-visual. When the attributes in which we wish to perceive patterns are non-visual and not obviously convertible into visual form by any simple method, we are cut off from the superbly efficient, intuitive system which we have developed for sorting visual signal patterns. It is thus understandable that psychologists and bacteriologists have been leaders in attempts to develop numerical methods to substitute for visual ability in classifying. The attempts, so far, are somewhat unsatisfying, not only because they involve algorithms which may be different from our intuitive systems, but because they may yield different results. It therefore seems desirable to attempt to understand the intuitive mental procedures we follow to recognize and compare patterns, even though the mechanism by which we carry out the procedures remains unknown.

One of the many problems is to determine the procedure by which we judge one-dimensional similarities (that is, similarities among pairs of states of a single attribute). The method by which we distinguish qualitative similarity is obviously related to discriminatory ability. Things which we can discriminate between are 'different'; things which we cannot discriminate between are 'one' or 'the

same'. This has been the basis of most numerical taxonomy so far. Single attributes are considered only as having qualitative similarity (0, 1 or +, -). In some instances similarities among single attributes have been scaled by considering them as sums of qualitative similarities (+++, ++-, +--, ---). Methods for weighting the sums have also been used¹. However, so far as we can determine, no one has proposed a satisfactory definition for what is meant by quantitative or fractional 'similarity' in a single dimension².

The key to solving this problem lay in the use of a model. We assumed (hopefully without distortion) that states of any single attribute (values in a single conceptual dimension) were ordered and monotonically related to distance in a single Euclidian dimension. We then considered similarities among a number of lengths (distances in one dimension). Considering hypothetical, exact lengths, it became clear that quantitative similarity is not a function of discriminatory ability. The uncertainty in an estimate of similarity is related to discrimination, but the size of the estimate need not be. It was also obvious that quantitative similarity must be relative, since there is no similarity (other than 0 or 1) when one considers only two states in the absence of other states or a base line of some kind.

If you ask a person: "How similar are lengths of 1 and 2 units?" he may tell you they are 1/2 similar. This sounds as though similarity is simply the ratio of two lengths. Other people, given the same task, will say that the lengths have no similarity, or they will avoid answering in terms of similarity, indicating that they do not have any basis for judging this relationship. If you give a set of three lengths, $A=1$, $B=2$, and $C=12$ units, and ask how similar are A and B , most people will say that they are quite similar, and will volunteer that A and B are more similar than A and C and further that B and C are more similar than A and C . There is no doubt in most minds about the rank order of the three pairs.

Similarity is obviously a ratio or proportion of some kind. But a proportion of what? We arrived at the answer to this question, appropriately enough, by gradually recognizing that we had backed past it some time before. As one of a number of attempts to code attributes in some way so that similarities could be weighted, we had tried the relation:

$$S_{AB} = \frac{L - |A - B|}{L} \quad (1)$$

where S_{AB} is the similarity of states A and B , and L is the distance between the most dissimilar pair of states (C and D) in the set being considered. In our length model, the 'state of A ' is the value of length A in the arbitrary scale units used.

Equation (1) specifies that similarities are fractional, that they range between 0 and 1, and that they are valid only within a given range of states. If the set of lengths is enlarged so as to increase the distance between the most dissimilar pair, the original fractional similarities must be shifted towards 1. Although the fractional values change, the rank order of the similarities does not (that is, the shift is monotonic). Thus, speaking of relative similarity is redundant, since all similarities are relative to some explicit or implied range. However, we would like to retain the expression 'relative similarities' as a

term for a 'set of similarities computed according to a single procedure for a specific set of things'.

Going back to the similarity between lengths of 1 and 2, we see that those who said they were half similar assumed that the lengths were a sample from a set ranging from 0 to 2, while those who said there was no similarity assumed that they were a sample of a set (or the whole set) ranging from 1 to 2. The inclusion of a third and longer length in the set increased the range and increased the similarity of lengths one unit apart.

Verbalizing equation (1) we see that 'similarity is the fraction of the considered range not included between two states'. We now accept this as the definition of similarity in one dimension, and suggest that if you substitute 'things' for 'states' in the foregoing definition, you have a good general definition for the intuitive concept of similarity in any number of dimensions. One reason that this concept has been so elusive is that the numerator is defined by stating what is not (the considered range not included). There was no word for this quantity and we propose that it be called 'undifference' (U). Undifference is the quantity which relates the distance that does exist between a pair of states to the distance that could exist between them. Or, stated another way, undifference is the distance that a pair of states is not apart. The intuitive idea that a pair of identical states drawn from a short set is not as undifferent as a pair of identical states drawn from a long set does not apply to hypothetical lengths, because we can distinguish an infinite number of such lengths in either a short or a long set. In the hypothetical case, the following relations hold:

$$\begin{aligned} L &= |C - D| \\ U_{AA} &= L - |A - A| = L = U \text{ for this system} \\ U_{BB} &= L - |B - B| = L \\ U_{AB} &= L - |A - B| \\ U_{CD} &= L - |C - D| = 0 \end{aligned} \quad (2)$$

and hence equation (1) can be rewritten as:

$$S_{AB} = \frac{U_{AB}}{U}$$

Although the undifference is defined only to within an arbitrary, multiplicative constant (the scale used to define the states), the relative similarities are uniquely defined since the same scale is used for A , B , C and D . Undifference, as described here, was clearly anticipated by Reynolds' in his recent article on comparative elaborateness.

When we wish to use a concept, such as length, to indicate something about the nature of a real thing, uncertainty arises. We can stipulate, and hence know for certain, the state of a concept; but real things do not exist in our conceptual dimensions and states, they exist in reality (whatever that may be). Therefore, our only recourse is to stipulate tests or measures (physical sorting systems) which yield signals (measurements) which we will interpret as data (states) which we assume are applicable to our concept. A number of measurements, made by repeatedly applying the same measuring procedure, may be treated statistically to yield a mean value and a probability that the next measurement made by the same system would fall within a given distance of the mean. Unfortunately, statistics may not tell us whether our concept of what we are measuring fits what we actually are measuring, but this need not lead to error, so long as the deficiency is recognized. There are, then, two sources of uncertainty: (1) Lack of precision due to measuring error, (a) where imprecision is independent of the magnitude of the measurement over the range being measured, and (b) where imprecision is related to the magnitude over the range being measured. (2) Lack of precision due to inapplicability of the measuring system (non-unidimensionality in the quantity being measured, *vide infra*).

Let us assume first that the best estimate we can get for the state (value in arbitrary units) we are trying to determine is the mean or average of the measurements. It would seem reasonable to determine relative similarities according to these means. Thus, for equation (1) we could substitute:

$$S_{AB} = \frac{L - |\bar{A} - \bar{B}|}{L} \quad (3)$$

where

$$L = |\bar{C} - \bar{D}|$$

or perhaps

$$L = C_{\max} - D_{\min}$$

The multiplicative constant for U is now restricted by the number of states that we can reliably discriminate between. We can put any interpretation we like on 'reliably', but we suggest a confidence limit of, say, 99 per cent (where $P < 0.01$). If we wish to make our sets of relative similarities comparable to one another, then the important criterion is to have comparable P s in the different sets. By being conservative we can also minimize the likelihood of overweighting similarities where P is calculated, compared to similarities where P is judged intuitively. The confidence limit of the mean of a number of measurements is related to the unit standard deviation, so that we could calculate the undifference at $P = 0.01$ for an identical pair of means \bar{A}, \bar{A} , on a scale of length L . However, this comparatively elegant method is computationally difficult and probably unwarranted for the usual number of measurements used to compute values for states. Also, we will usually have a number of sets of similarities where U is judged intuitively. When the measuring error is approximately constant over the given range of values (case 1a), we would prefer to assume that P will be sufficiently small if we let A_{\max} be the highest measurement for A , and A_{\min} the lowest,

$$\text{and} \quad R_A = A_{\max} - A_{\min}$$

$$\text{and} \quad \bar{R} = \frac{R_A + R_B + \dots + R_t + \dots + R_n}{n} \quad (4)$$

$$\text{and} \quad U = \frac{L}{\bar{R}} \approx U_{AA} \approx U_{BB}$$

When we estimate, or judge, the states of a non-numerical attribute, and distribute them among a number (n) of ordered classes that are intuitively equally reliable, then the undifference of the system, U , is given by the number of class intervals ($n - 1$), and this may be taken as the scale length, L , for use in computing similarity. Since n and U depend on the number of equally reliable (but not necessarily equally probable) states that an attribute can exhibit, we suggest that they are measures of the relative information content for classification. If we wished to sum sets of similarities to obtain an overall similarity, then the one dimensional similarities could be appropriately weighted according to:

$$W_{SAB} = \log_2 (U + 1) = \log_2 n \quad (5)$$

For measured states, where the measuring error is not constant, but is a function of the value of the mean (case 1b), one procedure would be to compute a separate U for each pair of states by assuming that the relation:

$$U = \frac{1}{2}(U_{AA} + U_{BB}) \quad (6)$$

holds good. This would mean, in effect, that the similarities in one relative set would be based on different numbers of classes and would have different weights. To avoid this intuitively unsatisfying arrangement, and to simplify computation, it would seem better to transform the scale used, so that the error in scale units is independent of the mean of the state. We could then proceed as for case 1a. For estimated or judged states, we would intuitively compensate for value-dependent errors when we form equally reliable classes.

Fig. 1. A-G. Models of an attribute (y), in which the state varies over another dimension (x). a-g, Histograms derived by taking 15 measurements of y randomly distributed over x .

When the spread of values, on repeated measurement, is larger than we would expect the measuring error to be, we would assume that non-unidimensionality of the attribute is the cause. Let us assume that the error in the measuring system can be estimated. We can then make a scale of a number of classes of equal confidence and small P . If repeated measurements fall into more than one class, lack of unidimensionality is present (case 2). To illustrate this point, consider the irregular bars in Figs. 1A-G. If we assume that each of these bars has a height, in arbitrary classes on the y axis, and we repeatedly measure the height at random over the x dimension (axis), we will get the histograms shown in Figs. 1a-g. The shapes of the bars define the histograms; but if we do not know how the y measurements are distributed over the x dimension (even whether they are random or not), the histograms do not uniquely define the shapes of the bars (for example, where y is spore-length and x is the reason(s) why different spores are not the same length).

Following our previous rationale, the procedure in this case would be to compute similarities on the means for the y measurements, and the undifference as in equations (4).

Another, more presumptuous, approach would be to assume that the distribution of frequencies in the histograms had some meaning which should affect the similarities as well as the weights. With this assumption we could compute a similarity based on the undifference of each measurement in each class of A compared with each measurement in each class of B. To compute this kind of similarity we would: let the state of A be an array of frequencies, $A_1, A_2, A_3 \dots A_i \dots A_n$; and the state of B be an array of frequencies, $B_1, B_2, B_3 \dots B_j \dots B_n$; and the sum of the frequencies of A be called F_A ; and the sum of the frequencies of B be called F_B ; and the range or scale-length, $n-1$, be called L . Then the similarity of A and B is given, when $F_A = F_B$, by:

$$S_{AB} = \frac{\sum_{i,j=1}^n A_i B_j (L - |i - j|)}{\frac{1}{2} \left[\sum_{i,j=1}^n A_i A_j (L - |i - j|) + \sum_{i,j=1}^n B_i B_j (L - |i - j|) \right]} \quad (7)$$

or rewriting the above equation in simpler notation,

$$S_{AB} = \frac{U'_{AB}}{\frac{1}{2}(U'_{AA} + U'_{BB})} \quad (8)$$

When $F_A \neq F_B$, we can correct by expanding to:

$$S_{AB} = \frac{U'_{AB} \cdot F_A \cdot F_B}{\frac{1}{2}(U'_{AA} \cdot F_B^2 + U'_{BB} \cdot F_A^2)} \quad (9)$$

This equation maintains the general relation that similarity is the fraction of the range not included between the states, but both the 'range' and the 'distance' between the states are affected by the spread of the values about the means of the states. Secondly, this equation stipulates that frequencies-in-common, or close frequencies, are more important in contributing to similarity than more widely separated frequencies are important in detracting from similarity. The equation does not assume a normal distribution of frequencies, and the results with skewed distributions are intuitively satisfying. The high similarities yielded with very broad spreads or bimodal distributions (because of the second effect already noted) are somewhat disturbing intuitively. The generally higher similarities that result when we use frequencies, rather than means of single values, are reasonable enough, since the similarity is still zero when all values fall in the two most distant classes.

Not only does increasing spread result in increasing similarity, but the spread of the states results in an effective compression of the range and this should be recognized in computing the weighting of the similarity. This is easily accomplished by modifying equation (5) so that:

$$W = \log_2 \left(n \cdot \frac{\frac{1}{2}(U'_{AA} + U'_{BB})}{U'_{\max}} \right) \quad (10)$$

where $U'_{\max} = F_A \cdot F_B \cdot L$

which, if $F_A = F_B$ simplifies to:

$$U'_{\max} = F^2 \cdot L$$

When we know the way in which the y measurements are distributed over the x dimension, we would probably not want to use either of the foregoing methods. For example, if y represents growth rate and x represents different known temperatures, one could compute a similarity for the growth rate at each temperature used. How many temperatures (values of x) should we use to

compute an overall similarity for growth rate (state of y)? Obviously the range of temperatures is limited by the lowest and highest temperatures at which any of the strains will grow (that is, the only useful values of x are those for which not all the y values are identical). The number of temperature values, within this range, which would contribute new information about the distribution of y over x , is limited by the minimum temperature difference which would produce growth rates between which we could reliably discriminate. Thus, we have a finite number of test classes, as well as attribute classes, and the number in each case is based on equally reliable discrimination within the range found. If we compute a set of similarities for an attribute, in each of a number of test classes, in each of a number of test dimensions, then we would need a weighted mean similarity for the attribute under all test conditions in order to compare it with, or add it to, similarities for other attributes. The relative weight of such mean similarities for single attributes should be the log of n for the whole attribute-test system, rather than the sum of the log n 's in each test class of each test dimension (compare equation (5)).

We have promulgated a principle for determining similarities in one dimension and devised some methods for applying it to attributes to yield sets of relative

similarities and weights. An obvious way to produce, from these, sets of overall similarities (\bar{S}_{AB} 's) is to let:

$$\bar{S}_{AB} = \frac{\sum_{i=1}^n S_{AB_i} \cdot W_{AB_i}}{\sum_{i=1}^n W_{AB_i}} \quad (11)$$

The weights of the overall similarities should be the sums rather than the averages of the weights for the individual similarities.

The matrix of weighted, overall similarities then needs to be transformed into a useful classification. One promising approach appears to be through multidimensional scaling³⁻⁵. This approach might even be able to compensate for the defect that the supposed one-dimensional similarities contain varying redundancy when summed.

A.C. RESISTIVITY OF ANODIC OXIDE FILMS ON VALVE METALS

By DR. G. C. WOOD and C. PEARSON

Corrosion Science Division, Department of Chemical Engineering, Faculty of Technology, University of Manchester,

THE frequency dispersions of a.c. resistivity of anodic oxide films on niobium, tantalum, aluminium, zirconium, titanium and tungsten have been measured and also the resistivity profiles through films on niobium by an extension of the technique of Heine and Pryor¹.

Specimens in the form of sheet or as the ends of wires were generally chemically polished, followed by a 10-sec etch in 40 per cent HF in the case of tantalum and niobium. Aluminium, however, was simply etched in 0.5 N NaOH solution for 15 min at 20°C followed by a 1-sec dip in 50 per cent HNO₃ at 90°C, and zirconium was finished on 1 μ diamond suspension. The specimens were anodized, generally in 3 per cent w/v ammonium tartrate solution (pH adjusted to 7), at 10 m.amp/cm² to an appropriate cell voltage followed by current decay, or occasionally to a given overpotential. The frequency dispersions of impedance of as-formed films or of films thinned in 1 per cent HF were measured, generally in tartrate solution, using a General Radio capacitance measuring assembly type 1610-B with a 50-mV p - p signal. This permitted the calculation of resistivities, on the assumption of the validity of a simple electrical analogue for the film of a resistor in parallel with a capacitor at any one frequency. Such results are plotted as bold curves in the diagrams; dotted curves, where included, indicate the effect of correcting for double-layer resistance by the simple method of Heine and Pryor¹. Thinning was judged to be macroscopically and microscopically uniform from interference colours and transmission electron microscopy respectively. As-prepared films seemed flaw-free and the flaw density was so low in thinned films that there appeared to be negligible effect on the impedance. The film capacitance was a sound measure of film thickness when compared with interference-colour determinations.

Fig. 1 shows the frequency dispersions of average a.c. resistivity for films 230, 1150 and 2300 Å thick formed on zone-refined niobium (purity better than 99.99 per cent except for about 100 p.p.m. tantalum) at 10 m.amp/cm²,

cm², followed by appropriate current decay to a residual current of less than 20 μ amp/cm². Clearly the thicker the film the higher the average resistivity. This could suggest either that the films become more perfect the thicker they grow, or that the resistivity of the film region adjacent to the metal is lower than elsewhere. Evidence presented here favours the latter interpretation. The observation seems to be a general one for valve metals, because it holds at all frequencies for tantalum and niobium in aqueous and non-aqueous solutions and for aluminium in non-aqueous solution. It is also true for aluminium and zirconium in aqueous solution at 10 kc/s and above. The curves converge at and below 1 kc/s for aluminium in aqueous solution, probably because of effects due to gross impurity substitution of OH⁻ ions^{1,4}, and for zirconium possibly for similar reasons. The phenomenon could not be checked for tungsten because the films thinned or showed strange behaviour during and immediately after formation in many electrolytes, or for titanium because a sufficient range of film thicknesses could not be obtained. For niobium, and particularly for tantalum, the results were relatively independent of metal purity (99.8 per cent to zone-refined), anodizing electrolyte and whether the main anodizing current density of 10 m.amp/cm² was terminated abruptly or by current decay.

Figs. 2a and b give the average resistivities at 1 kc/s and 100 kc/s respectively, measured after various stages of thinning by 1 per cent HF, for a 2300 Å film formed on zone-refined niobium. Each point plotted represents the average value for the film of that thickness remaining on the specimen, not the resistivity of a small element of oxide in that location¹. Results for 230 Å films thinned in 1 per cent HF and in M.Na₂CrO₄ solution with pH adjusted to 11.2 with NaOH solution (representing a much slower thinning rate) were quite similar. The various results indicate low-resistivity oxide adjacent to the metal at both frequencies, confirming the trends reported here. According to the Heine-Pryor theory¹, this represents an n -type semi-conducting region containing oxygen ion

Fig. 1. Frequency dispersions of average resistivity for anodic oxide films on niobium. \circ , 230 Å; \triangle , 1150 Å; \square , 2300 Å

vacancies or possibly excess metal ions. The associated partly trapped electrons required for electrical neutrality produce principally electronic relaxation effects observable at both frequencies. Presumably this represents a steady-state situation because it is held² that about 70 per cent of Frenkel defects present during formation rapidly disappear on stopping the current. When the results at 100 kc/s, corrected for double-layer resistance, are plotted as equivalent parallel resistances, R_p (obtained by multiplying the resistivity by the thickness at each thickness), a smooth non-linear curve is obtained. If R_p is plotted against the square of the thickness, a straight line passing through the origin is obtained, indicating that the number of these n -type defects varies with the inverse distance from the metal/oxide interface for the entire film, according to the theory of Heine and Sperry³. This contrasts with films on aluminium where the metal-deficient region extends only 60–80 Å into the film for 240 Å films^{1,4}. These preliminary results require confirmation, but the difference might be due to the greater solubility of oxygen in niobium. The undulations in the outer regions at 1 kc/s may be genuine because they are semi-quantitatively reproducible, but further work is required to explain them. The initial drop was originally thought to be due to opening of flaws by the HF, but simple calculations of the contribution of conduction down the few flaws to the overall impedance do not support this argument. The average resistivities at both frequencies for films thinned to 1150 Å and 230 Å respectively agree within experimental error with the corresponding values for films formed only to these thicknesses. If films on all the valve metals could be thinned uniformly (which is doubtful), it is probable that resistivity profiles of the general form shown would always be found. Similar, but not identical, curves have been obtained for aluminium in non-aqueous solutions⁴, which should prove more amenable to quantitative interpretation than the more complex ones obtained on partially hydrated films formed in aqueous solutions^{1,4}.

Fig. 3 presents a comparison of the frequency dispersions of average a.c. resistivity of 230 Å films formed on the various metals. Table 1 lists important constants for the metal oxides obtained from many sources. The values of dielectric constants used to calculate the appropriate

Table 1. IMPORTANT CONSTANTS FOR ANODIC OXIDE FILMS ON METALS

Metal and oxide	Dielectric constant	Melting point of bulk oxide (°C)	ρ Factor (metal ion radius) (oxygen ion radius)	Refractive index	\bar{A}/V ratio
Aluminium (Al_2O_3)	8–10.5 (8)	2,050	0.38–0.39	1.52–1.67	10–14 (12)
Zirconium (ZrO_2)	22–24.7 (22)	2,700	0.60	2.13–2.2	21–25.6 (25)
Tantalum (Ta_2O_5)	27.6	1,870	0.52–0.56	2.12–2.3	17.5
Niobium (Nb_2O_5)	41.4	1,520	0.52–0.54	2.22–2.46	23
Tungsten (WO_3)	41.7	1,473	0.47	2.2	18
Titanium (TiO_2 ?)	12–114 depending on form of TiO_2 (107)	1,640	0.52	2.5–2.9	20–50 (20)

resistivities and the \bar{A}/V ratios used to estimate film thicknesses are given in brackets where a range of values is quoted. Clearly, the lower the dielectric constant of the film the higher its a.c. resistivity. In order to obtain the curves presented it was necessary to know the dielectric constants of the films and their \bar{A}/V ratios. The only case of uncertainty is titanium, where both parameters are not well defined and a variety of curve positions can be obtained. The curve for tungsten (not included) lies near that of niobium (similar dielectric constant) but rather below it because the film tends to dissolve. Now, Young⁵

Fig. 2. Average resistivity measured during thinning of 2300 Å film formed on niobium. *a*, 1 kc/s; *b*, 100 kc/s

Fig. 3. Comparison of frequency dispersions of average resistivity for 230 Å films formed on various metals. ■, Al; ▴, Zr; ○, Ta; □, Nb; ▲, Ti.

has suggested that the higher the dielectric constant of the film, the lower its ionic resistivity. Although the a.c. resistivity measured with a low applied alternating voltage is complex, probably receiving contributions from several conducting processes, and is not necessarily directly related to the ease of ion movement under forming conditions at high direct voltages, the same trend seems to hold.

High a.c. resistivity (low dielectric constant) appears related to high oxide melting point (refractoriness), with titanium and zirconium as exceptions. The melting points quoted are, of course, for bulk oxides and do not necessarily apply to thin anodic films which are generally neither pure nor fully crystalline. The curve for the anodic film on zirconium may be out of position on the melting point criterion due to the film's greater tendency towards crystallinity. In any case, the thin-film, glass-forming characteristics (apparently favoured by a small ratio of metal ion radius to oxygen ion radius (ρ factor) but not well understood⁵) may be important and modify any criterion related to bulk melting point alone. Thus, Al_2O_3 would be expected to be a better glass-former than ZrO_2 on the basis of ρ factor, although it does not vitrify readily in the bulk state, and this may partly explain their relative resistivities. Apparently Ta_2O_5 and Nb_2O_5 should have good glass-forming characteristics but may be restrained from acting in this way by high ρ factors⁵. The low resistivity of TiO_2 is said to be more likely due to poor glass-forming characteristics than to impurities⁵. However, anodic films on zirconium and titanium are notoriously leaky compared with those on other metals, which may account for their behaviour. There appears to be little direct trend of a.c. resistivity with either refractive index or A/V ratio, which is not surprising.

Very recent consideration of the foregoing results, in the light of apparently more precise film and double-layer equivalent circuits, methods of determining point resistivities through the film and of applying the double-layer impedance correction, indicates that there may be a need to modify the absolute values of resistivity given here. Because of their complexity, these ideas will have to be elaborated in detail elsewhere⁶. Most of the foregoing trends still hold, but the theory based on the simple model may require some modification in due course.

COLOUR OF 'PURE' WATER*

By DR. JOHN E. TYLER

Visibility Laboratory, Scripps Institution of Oceanography, University of California, La Jolla

IN a previous article¹ a method was described for obtaining a fundamental specification of the colour of ocean or lake water, independent of the spectral variation of the natural lighting and independent of the spectral sensitivity of the photodetector.

The method consists essentially of three steps: first, the choice of suitable geometry for measuring the input flux to the body of water and the output flux from the water to the instrument; second, the measurement of a fundamental spectrophotometric property of the water body (which has been called the output/input ratio); and, third, the computation from these data of the trichromatic coefficients of the water colour. This method has recently been used to determine the colour of the exceptionally clean water of Crater Lake.

* The results used in this article were obtained during the course of research on optical methods for *in situ* detection and estimation of chlorophyll and other pigments in the ocean, a research programme which is supported by the U.S. National Science Foundation, Earth Sciences Division.

Crater Lake is the principal feature of Crater Lake National Park, a U.S. National Park in South-western Oregon. The lake is 20 miles in circumference, about 2,000 ft. deep, with its surface at an altitude of about 6,000 ft. It has no inlet other than rain or melting snow. The surrounding crater wall is sparsely vegetated and sparsely populated by wild animals, so that contamination from these sources has been small. One of the outstanding characteristics of the lake is its unusual blue colour, which is, of course, a consequence of its lack of contamination.

In 1940 the lake was examined for phytoplankton and particulate matter by Utterback and Phifer². They found that, "In the upper 20 metres of the lake, there was practically no phytoplankton . . .". They also noted that the water contained small particles of volcanic glass, but they did not undertake to determine the vertical distribution of these latter particles.

In this work, the colour of Crater Lake was measured with the same instrument used to obtain the data of the previous publication¹. The instrument was mounted underneath a small raft with the irradiance plate for measuring the input flux to the water just above the water surface, and the axis of the underwater collection system oriented horizontally. Generally clear, sunny weather prevailed during the measurements.

The average output/input ratio data for Crater Lake, shown in Fig. 1, were obtained from a location off an island near the west side of the lake. The instrument was oriented to point in a north-westerly direction in order to avoid the forward scattered flux from the Sun's direct rays.

Although it is valid to specify the colour of the water for any chosen direction, it is more difficult to obtain a satisfactory measurement in the Sun's direction because the forward scattered component of the sunlight rapidly changes in magnitude as the Sun changes its position relative to the instrument's direction of observation. With the Sun behind the instrument, repeated measurements taken an hour or more apart showed no significant changes in the output/input ratio due to the changes in the Sun's position.

Fig. 1. Average output/input data for Crater Lake (August 23, 25, 1964)

The data of Fig. 1 have been used, together with the relative spectral distribution of the energy in sunlight above the Earth's atmosphere, to calculate the tristimulus values of the colour of Crater Lake water. This colour has been plotted in the C.I.E. co-ordinate system in Fig. 2, and from the plot the following colorimetric specification has been obtained:

Dominant wave-length: 483 mμ
Photometric brightness: 91.7 per cent
Purity: 56.0 per cent

One of the interesting features of this method for determining the colour of the ocean or a lake is the ability to make accurate comparisons of the colour of remotely separated water bodies. The cleanliness of Crater Lake can be immediately deduced from Fig. 2, and the extent of the chlorophyll contamination in the other waters illustrated can be comparatively judged. If data were available, it should also be possible to distinguish

Fig. 2. C.I.E. plot to show colour of Crater Lake water relative to sunlight outside the Earth's atmosphere as a reference standard. The other points represent water containing chlorophyll (see ref. 1)

red algae from green, since these colours would occupy characteristic regions of the diagram.

One objective of this work was to obtain output/input data on the purest water that could be found. Such data could then serve as a standard, against which to estimate the contamination of other waters. There are, no doubt, many bodies of clean water which will compete for the 'honour of being the purest', and further measurements will have to be made if the ultimate standard of purity is to be found.

It is possible, however, to make one interesting comparison. In 1930, Beebe³ published a paper in which he described the spectra of the spacelight observed in a horizontal direction under water. Beebe's observations were visual, and consequently must be interpreted with care, since, for the greater depths at which he worked, his vision was scotopic and the spectral sensitivity of his eye would have been shifted considerably. On the other hand, at a depth of 800 ft., the selective absorption of light by water must have converted ordinary daylight into nearly monochromatic light. If we assume that this was the case, then we can deduce from Beebe's observations that the minimum value of the attenuation coefficient for Bermuda water occurred at 520 mμ.

From Fig. 1, the minimum value of the attenuation coefficient for Crater Lake is at about 450 mμ. It follows, therefore, that Crater Lake water in 1964 was bluer and cleaner than was the water off Nonsuch Island in 1930.

For the detection and estimation of specific pigments such as chlorophyll, it is of course more useful to work directly from the output/input data rather than from the colour of the water. References to papers on this subject are given in refs. 4 and 5.

I thank the staff of Crater Lake National Park, especially R. A. Nelson, superintendent, Donald Robinson, assistant superintendent and R. M. Brown, chief park naturalist, for their help.

RELATIONSHIP BETWEEN THE ELECTROMYOGRAM AND THE FORCE OF THE ISOMETRIC REFLEX RESPONSE OF NORMAL HUMAN SUBJECTS

By ALEX M. CLARKE*

Department of Psychology, Australian National University, Canberra

EARLY research by physiologists revealed a correlation of electrical (motor unit) activity with muscular contraction in spinal and decerebrate animals as well as involuntary contractions in man¹. Since then many reports have appeared in the literature to show that surface electromyograms (EMG) bear a linear relationship to the magnitude of voluntary muscular tension under conditions of isometric contraction²⁻⁴. However, no observations appear to have been reported of a relationship between the magnitude of the isometric response in a myotatic stretch reflex and EMG in man.

In the experiments described here, the knee-jerk was selected for examination for the following reasons: (a) the neural linkage for the α -route at the lumbar region of the spinal cord is monosynaptic, thus providing a reasonably simple pathway⁵⁻⁷; (b) the response is remarkably restricted in scope at low levels of excitation⁸: the reaction is confined to the quadriceps femoris, while synergist and antagonist muscles usually are inhibited or unaffected; (c) the subject can sit and relax in a chair specially designed to hold him in a comfortable, standard, symmetrical position since body and limb positions are known to affect reflexes^{8,9}. There is adequate evidence to establish the functional dependence of the myotatic stretch reflex on the excitation of the primary (annulo-spiral or nuclear bag) ending of the muscle spindle which is exclusively innervated in mammals by small-diameter motor nerve fibres (γ -efferents)^{6,10,11}. In this way feed-back is provided which, although being too slow to monitor reflex movements, has a strong indirect influence on the spindles, biasing them for different tensions of extrafusal muscle and rates of movement^{12,13}. The γ -efferent system itself is regulated from a number of central nervous system structures, notably the mesencephalic, diencephalic and bulbar regions of the reticular formation¹⁴. In addition, γ -discharge has been found to relate closely with change in level of cortical activity so that spindle sensitivity, generally speaking, is controlled centrally by the degree of alertness or activation of the subject^{15,16}.

Therefore, in an attempt to reduce cerebral activity in the expectation of making γ -discharge at least more consistent than it is in normal circumstances, the three young normal male adults who were used in the experiments were trained to apply Jacobson's method of mental and physical relaxation¹⁷. At least six daily sessions of 1 h each were required to train the subject individually to reach the criteria of displaying: (a) quiescent EMGs, indicating supported and relaxed muscles before and after the mechanical tap to the ligamentum patellae¹⁸; (b) discrete, highly synchronous muscle action potentials in response to the stimulus¹⁹.

Figs. 1 and 2 show comparisons between the records obtained by trained and untrained subjects.

Testing was conducted in a sound-proofed, electrically shielded and thermally insulated room in order to control auditory and visual stimuli, room temperature and relative humidity, and to suppress 50 c/s electrical interference for EMG purposes²⁰. Silver disk surface electrodes, 11 mm diameter, with a shallow central depression were applied in standard positions 3 in. apart over the belly of the muscles, rectus femoris and biceps femoris. EMG signals were amplified through push-pull circuitry and fed to a Both pen recorder. Force records were obtained by amplification of signals from silicon strain gauges mounted on the pendulum-hammer and on the ankle cuff linkage.

* Commonwealth postgraduate research scholar.

Peak forces between 1.5 kg and 3.5 kg were applied to the ligamentum patellae by varying the height from which the hammer was dropped in some sessions and, on other occasions, the hammer was dropped from a standard height for a series of trials. Under the latter conditions, it was found that subjects could maintain consistent muscle tone over short periods involving about ten taps as indicated by uniform force records.

However, irrespective of whether there were variations in the force applied to the ligament (implying variations in the extension of the muscle), slight changes in muscle-resting tension, or consistent muscle tone, between trials

Fig. 1. Simultaneous electromyograms and force records showing electrical quiescence in the muscles of a trained and relaxed subject (G.B.). The discrete, diphasic potential in the EMG (rectus femoris) is the result of the tap on ligamentum patellae and indicates a high degree of synchrony in the discharge of muscle action potential. Negligible activity in biceps femoris.

Fig. 2. Simultaneous electromyograms and force records showing random electrical activity in the muscles of an untrained and tense subject (A.M.). Hump in the force record of the isometric contraction indicates that a clonus condition has occurred. The 'interference pattern' EMG is evident in biceps femoris.

* All correlations are significantly different from zero ($P < 0.001$).

in any one session, a high positive relationship was found between the impulse (the integral of force over time) of the isometric contraction, measured at the ankle, and the EMG impulse of the quadriceps muscle.

Table 1 provides data relevant to the product-moment correlations obtained between these two variables for the three subjects.

The explanation for this near linear relationship probably lies in the consistency of γ -innervation of the spindles under the experimental conditions imposed for these subjects and in the fact that there was no complicating activity from the flexor muscles. The γ -discharge causes the contraction of the intrafusal fibres and leads to a decreased threshold of the muscle spindle to stretch²¹. It is thought that in many instances, a reflex is augmented by an increase in γ -efferent activity²². Thus, fluctuations in the sensitivity of the spindles to stretch by variable activity of the γ -motoneurons in biasing the intrafusal muscle fibres would result in a greater or lesser number of spindle receptors firing when stimulated by the tendon tap at any given time. Assuming that the motor end-plates

of the extrafusal fibres fire proportionally to the number of spindles activated, then one may take the discrete, highly synchronous potential impulse of the EMG as the best, indirect indicator of the magnitude of γ -biasing of the spindles of the quadriceps muscle (rectus femoris). In view of the small standard deviations obtained in this variable, one might conclude that fluctuations in small fibre control of the stretch reflex response were minimal.

Some preliminary work on the correlation between the maximum force of the isometric contraction and the impulse has yielded correlations of the order of +0.992 which probably indicate that the reflex response is ballistic. In this event, the γ -innervation would be too slow to have any direct effect during the response; presumably the force-time relations of the muscle contraction under isometric conditions are programmed beforehand by at least such factors as the degree of sensitization of the spindles and the initial resting tension of the muscle. Triggering occurs when the mechanical tap imparts a sudden, brief stretch to the muscle.

Consequently, provided that there is no modification of the knee-jerk response by involvement of flexor muscles and if fluctuations in γ -control over spindle sensitivity are minimal, a high positive relationship would be expected between the EMG and the isometric contraction of the extensor muscles.

I thank Dr. J. R. Trotter for his advice.

PURINE RICH REGULATORY SEQUENCES IN MESSENGER RIBONUCLEIC ACID

By PROF. ROY H. DOI

Biological Research Laboratories, Department of Bacteriology and Botany, Syracuse University, Syracuse, New York

THE elegant proposal for the existence of a messenger RNA by Jacob and Monod¹ has been supported by evidence obtained from phage-infected cells²⁻⁵, step-down transition cells⁶⁻¹⁰ and log phase bacterial cells^{10,11}. The results from these systems indicated that a polynucleotide fraction had most of the properties postulated for a messenger RNA (*m*-RNA), that is, a short half-life^{6,12}, a DNA-like base composition^{6,10}, a heterogeneous size^{13,14}, an affinity to ribosomes^{15,16} and a sequence complementarity to DNA^{4,6}. However, there is still a paucity of results regarding the actual template function for protein synthesis of the *in vivo m*-RNA fraction. The

most definitive results have been obtained by using synthetic polyribonucleotides^{17,18} or phage RNA^{19,20} as messages. Synthetic polymers have been used for incorporation of specific amino-acids into polypeptides. The product made in the presence of phage RNA has polypeptides ordinarily found in the phage coat protein. In binding experiments, polynucleotides²¹⁻²³ and trinucleotides²⁴ attached to ribosomes have directed the binding of specific aminoacyl-transfer RNAs. These various studies have led to the present dogma that transfer of information from DNA to protein occurs through an *m*-RNA.

In this rapid advance in our knowledge of protein synthesis, it was felt that a critical analysis of the data available would produce some useful information on the

properties of *m*-RNA. A particular property of the *m*-RNA which could be analysed was the reported base compositions of the *m*-RNA fraction. Table 1 presents a list of organisms and the base compositions of the *m*-RNA fraction isolated from these organisms. Three criteria were used for inclusion of RNA base ratios in this Table. The RNAs were (a) hybridized to DNA^{4,44,50,57}, (b) synthesized after phage infection, or (c) synthesized during step-down transition. The RNAs studied were pulse-labelled or steady-state labelled with ³²PO₄ and analysed after alkali hydrolysis. Most of the RNAs were hybridized with DNA and separated from the bulk of the cellular RNA by differential sedimentation, column fractionation, or membrane filtration before analysis. Those RNAs not hybridized with DNA were obtained under conditions in which undetectable or very low levels of ribosomal and transfer RNAs were synthesized. A fact to remember is that these *m*-RNAs are heterogeneous populations.

The properties of the *m*-RNA in Table 1 can be summarized as follows:

(a) *Percentage of guanylate + cytidylate (%GC) or resemblance to DNA composition.* For most *m*-RNAs there is a resemblance of the %GC to that of the DNA. However, for many of them the %GC is significantly different from that found in the DNA. For *E. coli*, for example, the range is from 43.1 to 57.7 per cent. In *P. aeruginosa* the %GC of the *m*-RNA is much lower than that of the DNA. The deviation is less marked with the phage *m*-RNAs.

(b) *Percentage of adenylate + guanylate (%AG) or purine content of M-RNA.* All the RNAs except that from HeLa had a %AG of 50 \pm 2 per cent or higher. The *m*-RNAs have either an equivalence of purines and pyrimidines or are purine-rich in all the cases examined except one. Conversely one can state that *m*-RNAs are pyrimidine-poor. The DNA composition of the organisms analysed was from 34 to 66 per cent guanylate + cytidylate.

(c) *The adenylate-uridylylate ratio (A/U).* In most of the RNA populations the A/U ratio is equal to or greater than 1.0. In an extreme case the ratio is 1.47. If one considers a 2.0 per cent molar ratio difference between A and U as insignificant in the base composition analyses, one finds that in all cases the content of A is equal to or greater than U in *m*-RNAs.

(d) *The guanylate-cytidylate ratio (G/C).* Once again the G/C ratio is equal to or greater than 1.0 in all cases except for HeLa cells.

Before discussion of the possible significance of these facts, it is of interest to consider viruses, since viral RNA

Table 2. BASE COMPOSITION OF VIRAL RNA

Virus	Moles per cent							Ref.

has been shown in one case to act as an *m*-RNA¹⁹. On the assumption that some viral RNAs and perhaps all are indeed *m*-RNAs, attention is now directed to their base compositions. Table 2 lists the various viruses and their RNA base compositions. The properties of viral RNAs can be summarized as follows:

(1) *Percentage of A + G or the purine content of viral RNAs.* In all cases except for turnip yellow mosaic virus and the influenza viruses, the purine content is 50 \pm 1 per cent or significantly higher than 50 per cent. Many cases exist in which the purine content is 55 per cent. In the three cases in which the purine content is less than 50 per cent, the molar content of A + G is about 40 per cent.

(2) *The A/U ratio.* About two-thirds of the analyses show that the A/U ratio is equal to or greater than 1.0. Of the one-third in which the A/U ratio is less than 1.0, some have a ratio as low as 0.65.

(3) *The G/C ratio.* In all cases except for turnip yellow mosaic virus and the influenza viruses, the G/C ratio is equal to or greater than 1.0. An extremely low G/C ratio is seen with turnip yellow mosaic virus RNA.

Before these facts are related to present knowledge of *m*-RNA compositions, a pertinent question can be asked. What type of information is present in *m*-RNA? According to present coding theories, the codon for each amino-acid and the sequence of amino-acids in the polypeptide product are determined by the sequence of nucleotides in the *m*-RNA (ref. 25). Since the *m*-RNA interacts with ribosomes during protein synthesis in an ordered manner, a recognition or starting and stopping sites for translation may be encoded into the ends of the polynucleotide²⁴. Furthermore, evidence has been presented for polycistronic *m*-RNA²⁶⁻²⁹, that is, an *m*-RNA which codes for more than one polypeptide chain. If this is indeed the case, there must exist a mechanism which allows ribosomes to recognize the end and beginnings of the cistrons. This mechanism may allow ribosomes to separate from the *m*-RNA or it may allow the finished polypeptide chain for each cistron to separate from the ribosome which continues in the translation process³⁰. This mechanism may involve specific nucleotide sequences. Therefore the total base composition of an *m*-RNA population would reflect the composition of the codons for the amino-acids in the proteins and other sequences of nucleotides which in some way 'regulate' the translation process.

Two general compositional properties of *m*-RNA are significant: (i) *m*-RNAs appear to be either purine rich, or have equal contents of purines and pyrimidines; and (ii) the A/U and G/C ratios are higher than 1.0 except in one case. For viral RNAs, (a) the purine content is higher than the pyrimidine-level in most cases examined; (b) the G/C ratio is equal to or greater than 1.0 in all cases examined except three; (c) for the A/U ratio, only two-thirds of the virus RNAs had a ratio equal to or greater than 1.0; this is significantly different from the results with *m*-RNAs.

Is there any significance or relationship of these data to other facts which are known about the information transfer

process in living systems? From recent results obtained by a variety of techniques and by many investigators, certain information has appeared which seems to have relationship to the data presented in Tables 1 and 2.

Several groups have reported that only one strand of the double-stranded DNA is transcribed. Direct evidence has been obtained with phage systems in which phage specific *m*-RNA hybridized with only one of the two strands of phage DNA³¹⁻³⁴. This information-carrying strand has been the pyrimidine-rich DNA strand in all cases reported. Thus the phage *m*-RNA are rich in purine. This suggests then that the purine-rich *m*-RNA found in non-phage systems may also be significant. It implies that information carrying genetic sites may in all cases be rich in pyrimidine.

The high purine content of the *m*-RNAs examined so far suggests that adenylate and guanylate may be encoded into sequences of nucleotides regulating translation. Recent reports appear to support this contention. In investigations with aminoacyl-transfer-RNA binding directed by trinucleotides^{35,36} and polynucleotides³⁷, the sequences AGA and UAA did not support binding of any of the aminoacyl-transfer RNAs tested. The presence of two adenylates in both cases seems significant in view of the high adenylate content of natural *m*-RNAs. From a theoretical point of view (triplet code) an *m*-RNA with a 1.2×10^6 mol. wt. can code for six polypeptides of 2.0×10^4 mol. wt. If 3 per cent of the nucleotides in this polycistronic *m*-RNA were involved in regulatory functions and two-thirds of these nucleotides were adenylate, the distribution of bases would show that adenylate is present at a molar level 2 per cent higher than that of the other bases. This calculation is based on equal distribution of the remaining 98 per cent of the bases. The percentage of nucleotides involved in regulation may be proportionately even higher, since it was demonstrated recently that a naturally occurring *m*-RNA with 36 nucleotides coded for the *in vitro* synthesis of a polypeptide containing ten amino-acids³⁸. In addition, both terminal nucleotides of this natural *m*-RNA were adenylates. The low purine content of HeLa cell *m*-RNA may be significant, since in cancerous cells one might expect some deficiency in the regulatory mechanism. This deficiency is perhaps in the information-carrying DNA strand in which pyrimidine sequences are altered or decreased.

It would be of interest to learn whether triplets with two guanylates are inactive in binding. The triplet GGU was shown to bind glycine³⁵, but the results with the other possible sequences have as yet to be reported. As the G/C ratio is usually greater than 1.0 in *m*-RNAs and the genetic code appears to be universal²⁵, it is a possibility that in DNAs with high %GC, the G containing regulating sequences may be more abundant. In this respect, *P. aeruginosa* has an A/U ratio of 1.0 but a G/C ratio of greater than 1.0. In DNAs with high %AT, the A-containing regulating sequences may be more abundant.

The presence of regulating sequences containing A or G can be masked in many ways including high frequency of amino-acid codons which are low in A and G, large *m*-RNAs with few cistrons, or large cistrons with few regulating sequences. These and other reasons may be involved in masking the regulating purine content of RNA from RNA-containing viruses. Although degeneracy in coding probably alters the composition of the *m*-RNAs in different species, the recent work from Nirenberg's laboratory^{35,36,58} suggests that all four bases are involved with equal frequency. Furthermore, the purine relationship is seen in organisms with high and low %GC in their DNAs.

Although the proposal of regulatory sequences containing purines is hypothetical, the fact remains that well-characterized *m*-RNAs do have compositional properties which appear to fit a pattern. It is of added interest that this pattern holds true for bulk RNA compositions (ribosomal and transfer (RNAs) as tabulated by Belozersky and

Spirin³⁹. Recent advances on protein-synthesizing systems^{40,41}, on the use of natural RNA templates³⁸, and on RNA sequence analysis⁴² have indicated that direct experimental evidence should emerge soon to test this hypothesis.

CHANGES IN THE *t*-RNA METHYLATING ENZYMES
DURING INSECT METAMORPHOSIS

By DR. B. S. BALIGA, PROF. P. R. SRINIVASAN and PROF. ERNEST BOREK

Department of Biochemistry, College of Physicians and Surgeons, Columbia University, New York

A NUMBER of enzymes the function of which is the specific methylation of nucleic acids is now known to exist¹. While considerable information has been gathered about the mechanism of action and specificities of these enzymes, very little is known about the biological function achieved by the methylation of nucleic acids. That the methylation of DNA confers an individuality in one instance has been demonstrated by Arber², who found that host range modifications in λ -bacteriophage may be introduced by methylation.

For the enzymes which methylate *t*-RNA, the *t*-RNA methylases, no biological function has been found as yet. It has been demonstrated in our laboratory, however, that the RNA methylases can be profoundly altered in bacterial cells on phage infection or induction³.

Both the RNA and DNA methylases are species specific^{4,5}. We have speculated whether the species specificity of these enzymes may not point to their involvement in differentiation, a process requiring the greatest species specificity¹. We have now tested this hypothesis in an insect during its cycle of metamorphosis and wish to report that alterations occur in the *t*-RNA methylases not only at the transition from larva to pupa but also throughout the duration of the pupal stage right up to the emergence of the imago.

Collection of pupae and their development into adult beetles. *Tenebrio molitor* larvae were purchased from a local supply house and were maintained in open polyethylene trays on a diet of oatmeal, wheat bran and sliced carrots.

Prior to transformation into pupae, the larvae were found to have passed into an immobile phase close to the surface of the food bed. These were transferred to open glass trays and left at room temperature. Pupae were gathered from these trays daily at the same time. Pupae collected on a particular day were formed sometime during the preceding 24 h and were referred to as '1-day-old'. They were incubated at 28° in a humid atmosphere. About 50 per cent of these pupae developed into adult beetles on the seventh day. The process was nearly complete on the eighth day. Pupae ranging in age from one to seven days were picked up from these stocks and were used in the manner described below. The larvae were also collected separately and used similarly for assay of RNA methylases. (Methyl-¹⁴C)-*s*-adenosyl-L-methionine with a specific activity of 29.9 mc./mmole was purchased from New England Nuclear Corporation and diluted with non-radioactive *s*-adenosyl-L-methionine to give a concentration of 10 μ c. per 0.5 μ mole per ml.

Methyl deficient *t*-RNA was prepared by procedures previously published. Protein was estimated by the method of Lowry *et al.*⁶.

Preparation of enzyme extracts. Larvae or pupae were crushed and ground in a pre-cooled mortar with three volumes of a solution containing sucrose (0.25 M), magnesium chloride (0.001 M), and 2-mercaptoethanol (0.005 M). The homogenate was transferred into a Potter-Elvehjem type homogenizer. The mortar was washed with an equal volume of the extracting solution and the washings were added to the homogenate. The mixture was next homogenized for one minute with a motor-driven 'Teflon' pestle at 3,500 r.p.m. The homogenate was cooled for 5–10 min in an ice bath and the

homogenization was repeated for another minute. The homogenate was then filtered through cheese cloth and the filtrate centrifuged for 20 min at 27,500*g* in a refrigerated centrifuge. The faintly yellow-coloured supernatant was filtered to free it from membrane-like material floating on the surface. This filtrate, which contained 8–12 mg protein per ml. (depending on the stage of development of the pupae), was used as the source of enzymes for the methylation studies reported below. The enzyme extract was prepared fresh daily and was used immediately thereafter. All the operations connected with the preparation of the enzyme extracts were carried out in the cold (2°–5°) unless otherwise stated.

Assay of methylase activity. Methylase activity of the extracts was assayed by measuring the incorporation of ¹⁴C-methyl from (methyl-¹⁴C)-*s*-adenosyl-L-methionine into methyl-deficient *E. coli t*-RNA. The reaction mixture contained 50 μ moles *tris*-HCl buffer, pH 8.2; 5 μ moles MgCl₂; 5 μ moles 2-mercaptoethanol; 20 μ moles of (methyl-¹⁴C)-*s*-adenosyl-L-methionine (20 mc./mmole); 0.15 mg methyl-deficient *E. coli t*-RNA, water and the appropriate amount of enzyme extract in a final volume of 1.0 ml. Enzyme extract was added to the reaction mixture which had been pre-incubated at 37°. After 30 min, the reaction was terminated by the addition of 1.0 ml. of cold 10 per cent TCA followed by 3 ml. of 5 per cent TCA. The contents were cooled and centrifuged. The precipitate containing the protein and RNA was thoroughly agitated with 5 ml. of 5 per cent TCA, centrifuged as before and the supernatant discarded. The precipitate was similarly washed twice more with 5 ml. of TCA. Finally, the precipitate was dissolved in 1 ml. of 0.2 N ammonium hydroxide solution and was transferred quantitatively into stainless steel planchettes. The solution was evaporated to dryness under an infra-red lamp and the radioactivity measured in a Nuclear Chicago gas-flow low-background counter. Control experiments were simultaneously carried out in which RNA was omitted. The difference in radioactivity between the experimental and control tubes provided a measure of methyl groups incorporated into methyl-deficient *t*-RNA.

One unit of enzyme is defined as that amount which catalyses the incorporation of 1 μ mole CH₃ into *t*-RNA in 30 min under the foregoing conditions. Specific activity is defined as units of activity per mg of protein.

The amount of enzyme taken, 0.3–0.6 ml., was such that the methyl groups incorporated into *t*-RNA in 30 min did not exceed 40 μ moles. Within this range, the reaction was proportional to concentration of enzyme as well as to the time of reaction.

Extent of methylation. This was measured as in the assay of activity by incubating the reaction mixture for 4 h with 0.6 ml. of enzyme extract. No appreciable increase in methylation was noticed by incubating for a longer period.

In Fig. 1 the results of examination of the rate of incorporation of methyl groups into a methyl deficient *E. coli t*-RNA by extracts derived from larvae in their terminal stage and from pupae at various stages are presented. It is readily apparent that large changes occur in the activity of the *t*-RNA methylases almost daily within the pupae. The experiments were performed

Fig. 1. Activity of *t*-RNA methylases

on different batches of larvae and pupae over a period of several months, yet the pattern of enzyme activity is reproducible. A minimal activity on the third day is followed by a maximum on the fourth. On the seventh day, just prior to the emergence of the beetle, enzyme activity is at its lowest.

Another measurable parameter of the *t*-RNA methylases is the extent of methylation of the substrate, that is, the total number of methyl groups introduced by the enzymes in infinite time. Such determinations are presented in Fig. 2. Again large differences in total enzyme activity are apparent. For example, extracts from a 1-day-old pupa can seek out a little more than twice as many sites for methylation in *t*-RNA as extracts from a 7-day-old pupa. There is excellent concordance between the rates and total enzyme activity of the organisms in the same stage of their cycle of metamorphosis. Only in one batch of pupae (B VII) was there a 1-day discrepancy in reaching maximal activity in mid-pupa stage. The deviation from the norm by 1 day in this batch underlines the remarkable synchrony of the other batches of larvae and pupae.

Fig. 2. Extent of methylation

It is difficult to assess the biological meaning of these changes in enzyme activity. Interpretations are hindered by our lack of knowledge of the specific biological function of the methyl groups in *t*-RNA. Some regulatory function in protein synthesis for *t*-RNA has been suggested by Ames and Hartman⁷. Methylation of the *t*-RNAs is one method of altering these molecules for changing functions. If such should eventually prove to be the case, then the fluctuations in the *t*-RNA methylases during phases of metamorphosis will assume a new meaning and a search for the new proteins the syntheses of which are directed by the changing patterns of methylating enzymes could be undertaken.

Between the first and seventh day in the life of a pupa there is approximately a 50 per cent reduction in enzyme activity, whether it is measured as a rate or extent of

methylation. The natural question posed by this finding is the cause of the reduction: it could be due to some enzyme inhibitor, or the findings could also be accounted for by the appearance of a new nuclease which essentially eliminates all or part of the substrate. In Table 1 the results of experiments designed to probe these possibilities are presented. Various amounts of enzymes from 1-day-old and 7-day-old pupae were admixed and comparisons were made with respect to both rates and extents of the methylating potencies of the extracts. The addition of small amounts of the extracts of 7-day-old pupae which themselves have low activity does not seem to diminish the levels of activity of the extracts from 1-day-old pupae. However, on the addition of larger volumes of the extract from the 7-day-old pupae, the activity, especially in terms of the extent of methylation, does become diminished. It appears as if a certain concentration of some inhibitor must be reached before it becomes effective in interfering with methylation.

Table 1. ACTIVITY OF METHYLASES AND EXTENT OF METHYLATION. MIXING EXPERIMENTS WITH EXTRACTS OF 1-DAY-OLD AND 7-DAY-OLD PUPAE

Exp. 1				Exp. 2			
1-day-old pupal extract (ml)	7-day-old pupal extract (ml)	Activity	Extent	1-day-old pupal extract (ml)	7-day-old pupal extract (ml)	Activity	Extent
0.3		14.5		0.3		11.9	
0.6		57.2	89.5	0.6		34.1	95.5
	0.3	8.5			0.3	7.1	
	0.6	15.2	55.4		0.6	16.5	65.2
0.3	0.3	26.9		0.3	0.3	24.1	
0.6	0.3	40.4	103.4	0.6	0.3	36.6	80.5
0.3	0.6	31.2		0.3	0.6	36.0	
0.6	0.6	46.6	42.0	0.6	0.6	43.6	66.7

Activity is expressed as μ moles of methyl groups incorporated into 0.15 mg of *t*-RNA in 30 min. Extent is expressed as μ moles of methyl groups incorporated in 4 h. In these experiments the total volume of the reaction mixtures was 1.5 ml

Nuclease activity in extracts of the pupae was also examined as a possible cause of the alterations observed here. Even after incubation for 4 h with these extracts, very little, if any, nuclease activity could be detected. Therefore, the reduced capacity for methylation in the extracts of the 7-day-old pupa cannot be due to the diminution of the substrate but rather to some inherent attribute of the methylases, the nature of which is obscure at present.

A rather potent nuclease activity which cleaved *t*-RNA was detected occasionally in larvae. The appearance of this nuclease activity was correlated with the conditions of the housing of the larvae. The nuclease appeared and reached a maximum within a period of two weeks in larvae which were kept in a relatively dry atmosphere. Under these conditions, the process of pupation was slowed down and ultimately ceased altogether, resulting in the death of large numbers of larvae.

The almost daily alterations in the levels of the RNA methylases during the pupal stage are highly suggestive of some basic function. This is a period of extensive differentiation aimed at the production of the new tissues and organs of the imago. The *t*-RNA methylases alter the structure of one of the cardinal components of the protein synthesizing machinery of the cell. We have also observed changes in the *t*-RNA methylases in an entirely different biological system during upheavals in its metabolic pattern. Either in bacteria infected by T2 bacteriophage or in lysogenic bacteria after induction of the latent phage by ultra-violet irradiation, major alterations in the enzyme-levels as well as in the patterns of methylation have been noticed⁸. In other words, in both instances, as a result of changes in the methylating enzymes, alterations must occur in the relative amounts of the methylated bases in the *t*-RNA of the host cell. It is difficult to imagine that bacteriophage carry information within their highly limited volume to make alterations in one of the macromolecules of the host without some purpose. We must therefore search for some regulatory mechanism at the level of *t*-RNA which is triggered by methylation.

INFLUENCE OF HETEROLOGOUS HISTONE ON THE SYNTHESIS OF CELLULAR AND VIRAL RIBONUCLEIC ACID AND PRODUCTION OF HAEMAGGLUTININ

By A. G. BUKRINSKAYA, A. K. GITELMAN and I. M. SHAPIRO

Institute of Virology, U.S.S.R. Academy of Medical Sciences, and Institute of Animal Morphology, U.S.S.R. Academy of Sciences

IT has been shown that histones inhibit cellular RNA synthesis both *in vivo* and *in vitro*¹⁻⁴. This effect seems to be connected with the histone-induced blockage of DNA as a template. On the other hand, a protein of a histone type was found to be produced in a cell in the first hours after its infection with a virus. This protein inhibits the cellular RNA synthesis before the onset of the viral RNA synthesis⁵. The synthesis of histone in virus-infected cells increased during the first hours after infection⁶. These data suggest that treatment of the infected cells with histone may stimulate the viral RNA synthesis.

In the present work the action of histone on the synthesis of cellular and viral RNA as well as on haemagglutinin production and infectious properties of virus has been studied.

The experiments were carried out on monolayer cultures of chicken fibroblasts. Fowl plague virus (Weybridge strain) was obtained as allantoic fluid of eleven-day-old chicken embryos. In some experiments the virus was concentrated by one cycle of adsorption and elution on chicken erythrocytes. The multiplicity of infection was about 10 and 100 ID_{50} per cell, respectively. The period of adsorption was 30 min at 4° C; the same volume of balanced salt solution was added to the control cells. After washing, the histone in balanced salt solution was added, and the cells were incubated at 37° C; this moment was considered as zero time of the experiment. ¹⁴C-cytidine was added to the medium every hour or every half-hour after infection. The monolayers were washed, cells taken off the glass, pipetted, collected on 'Millipore'

filters, treated twice with cold 5 per cent perchloric acid, twice with cold 96 per cent ethanol, and dried. After counting, the 'Millipore' filters were dissolved in acetone, RNA was hydrolysed by 1.7 M HClO₄ for 18 h at 4° C and the radioactivity was counted per μ g RNA.

The total histone was isolated from the calf thymus by the method of Hnilica and Hupka⁷ in the Institute of Medical and Biological Chemistry, U.S.S.R. Academy of Medical Sciences.

In some experiments cells were incubated in the presence of 5-fluorodeoxyuridine (FUDR), 10⁻⁶ mole/ml. being added at zero time.

As can be seen in Fig. 1, histone inhibited ¹⁴C-cytidine incorporation in the acid-insoluble fraction during the first 2-3 h. The same results were obtained in the presence of FUDR. Hence this effect is connected with the inhibition of RNA synthesis.

The inhibition of incorporation (varying from 12 to 60 per cent of the control-level) occurred in the first 2 h after infection with the allantoic virus. The incorporation was maximal 4-5 h after infection and reached about 130 per cent of the control. When concentrated virus was used

Fig. 1

Fig. 2

Figs. 1 and 2. Rate of ¹⁴C-cytidine incorporation in acid-insoluble fraction of chicken fibroblasts. Radioactivity of histone-treated non-infected (□) and untreated infected (Δ) cells as percentage of the control, radioactivity of histone-treated infected cells (▲) as per cent of radioactivity of histone-treated non-infected cells. (1) Multiplicity of infection 10 ID_{50} per cell; each point is the average of 4 sets of experiments with 100 μ g/ml. of histone. 0.07 μ C-cytidine (specific activity 2.5 μ C per μ mole) were added in 2-3 flasks 0, 1, 2, 3 or 4 h after infection and left for 1 h. (2) Multiplicity of infection 100 ID_{50} per cell; one typical experiment with 150 μ g/ml. histone. 0.07 μ C-cytidine were added 0, 0.5, 1, 1.5, 2, 2.5 or 3 h after infection and left for 0.5 h

the minimal and maximal incorporation was found after 1 h and 2–2.5 h, respectively. Similar results with infected cells were observed in the presence of FUDR (Figs. 1 and 2). The inhibition of the incorporation seems to be caused by the formation of virus-induced repressor of cellular RNA synthesis while the stimulation of the incorporation represents the viral RNA synthesis⁸.

In the experiments with histone treatment the maximum of incorporation after infection with non-concentrated virus was higher than in the infected control, the minimum and maximum of incorporation were observed at 1.25 ± 0.3 h and 2.8 ± 0.43 h, respectively; whereas in the experiments without histone these intervals were 2.25 ± 0.3 h and 4.4 ± 0.28 h, respectively. The maximum of the incorporation in histone-treated cells infected with concentrated virus was lower than in infected controls and occurred 1 h earlier (Figs. 1 and 2). Thus, histone treatment brought about inhibition of cellular RNA synthesis and earlier synthesis of viral RNA. It may be supposed that heterologous histone acts similarly to virus-induced repressor. Their combined action inhibits cellular synthesis of RNA earlier and, probably due to this, earlier synthesis of the viral RNA occurs. There would seem to be a relationship between the time of the cellular RNA synthesis inhibition and that of the viral RNA reproduction.

The haemagglutinin titres and ID_{50} in histone-treated cells were lower as compared with infected controls (Table 1).

Table 1. HISTONE ACTION ON HAEMAGGLUTININ AND ID_{50} TITRES AT DIFFERENT TIMES AFTER INFECTION

Experimental series	Hours after infection					
	2	4	6	8	12	
Control cells	HA 0	HA 16	HA 32	ID_{50} $10^{7.6}$	HA 64	ID_{50} $10^{7.6}$
Histone-treated cells	0	2	4	10^7	8	16 $10^{7.0}$

Cells were infected with 10 ID_{50} per cell, thoroughly washed, and 100 μ g/ml. of histone were added at 0 time.

The cells were disrupted 12 h after infection by quick-freezing and thawing, haemagglutinin titres were determined in supernatant fluid with a 0.5 per cent suspension of chicken erythrocytes, ID_{50} titrated in chicken embryo pool and expressed as haemagglutinin units/ml. and ID_{50} /ml.

It is of interest to note that probably there is a comparatively narrow time-interval over which the addition of histone to the medium can influence haemagglutinin production. After the treatment of cells from 0 to 2 h, haemagglutinin titres were 8–16-fold lower than those in the control; when histone was added 3 or 5 h after infection, haemagglutinin titres were about the same as in the control. In three experiments histone was added

Fig. 3. Haemagglutinin production in relation to the time of histone addition. Each point is the average of 3 experiments. Cells were infected with 10 ID_{50} per cell and thoroughly washed, and 100 μ g/ml. histone were added 0, 1, 1.25, 1.5, 1.75, 2, 3 and 5 h after infection. The haemagglutinin titres were determined as described in Table 1.

to the medium every 15 min after infection. The most sensitive period to histone action was between 0 and 1.5 h after infection, the haemagglutinin titres were lowest when histone was added 1.5 h after infection (Fig. 3). Haemagglutinin production in this system starts 3 h after infection. Thus the most sensitive period was found much earlier than the process of haemagglutinin production started.

It is not yet known whether the cell genome takes part in haemagglutinin production of myxoviruses. That is why it is difficult to decide whether the effect observed is due to the binding of histone with DNA or viral RNA. Of interest is the fact that actinomycin D in low concentration (up to 2 μ g/ml.) has the same effect as histone on the synthesis of the viral RNA and haemagglutinin of PR8 and Weybridge strains of fowl plague virus^{9,10}.

SUPPRESSION OF THE PUPILLARY LIGHT REFLEX IN BINOCULAR RIVALRY AND SACCADIC SUPPRESSION

By M. LORBER*, DR. B. L. ZUBER* and DR. L. STARK*

Neurology Section, Electronic Systems Laboratory and Biology Department, Massachusetts Institute of Technology, Cambridge, Massachusetts

IN 1948 Bárány and Halldén¹ reported that the pupillary response to a flash presented to the non-dominant eye of a subject experiencing binocular rivalry was smaller than the response to the same flash presented to a dominant eye. We have sought to repeat these experiments using the direct-recording infra-red pupillometer² in order to get an objective measure of this suppression.

The subject's head was firmly held in front of the pupillometer by means of a bite board and head rest.

* Present address: Information Engineering Department, University of Illinois at Chicago Circle, P.O. Box 4348, Chicago

The right eye viewed a circular field of about twenty degrees in diameter which was dimly illuminated, and in the centre of which was a small fixation cross at optical infinity. The test flash, when it appeared, was superimposed on this field and had a duration of 10 msec. The fixation target for the left eye was a small dot at optical infinity and in the centre of a uniform field illuminated with a diffuse red light. The stimulus was delivered to the right eye every 3 sec, so that during rivalry flashes were alternately presented during dominance and non-dominance (reported by the subject, who controlled a two-position switch).

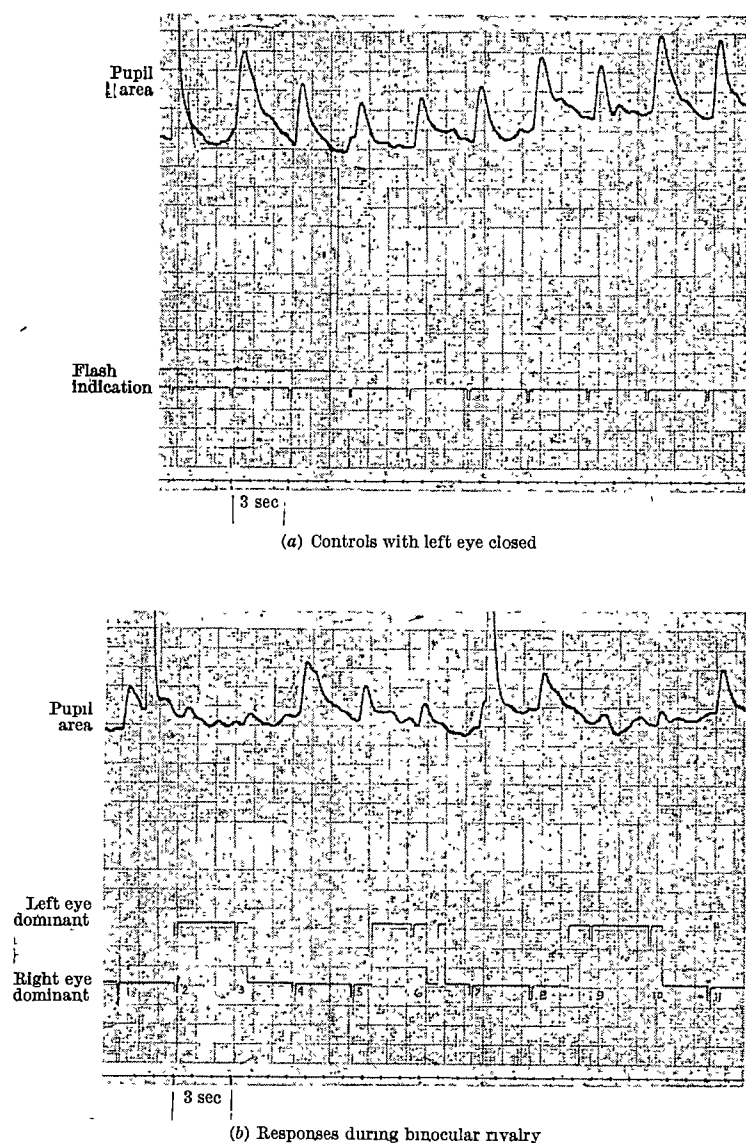

Fig. 1 Measurements of the pupillary response during binocular rivalry. *a*, Control responses with the left eye patched, *b*, responses during rivalry. Upper trace shows pupillary responses; broad shifts of base line on lower trace represent subject's state of dominance, narrow pulses indicate stimulus presentations

In Fig. 1*a* the responses to control flashes, taken with the left eye occluded, are shown. Fig. 1*b* shows responses during rivalry. Pupillary responses appear on the upper trace, while the subject's state of dominance (broad shift of the base line) and the occurrence of the stimulus (narrow pulses) are represented on the lower trace. On the whole, the responses during 'right eye dominant' are smaller than control responses, probably because the subject often experienced fusion of the two fields under this condition. There seems to be a significant decrease in the amplitude of the pupillary response when the right eye is suppressed (left eye dominant). These results have been confirmed by Richards⁹.

It has been well established that the visual threshold is significantly elevated just before and during a saccadic eye movement⁴⁻¹³. This phenomenon has been referred to as 'saccadic suppression'¹³. The experiments described here were designed to determine whether or not the pupillary light reflex is involved in this suppression.

The time required for the completion of a saccadic eye movement is short compared with the latency of the pupillary response. Thus the pupillary response to a flash presented to the moving eye may be measured by the pupillometer well after the eye has come to rest.

The stimulating apparatus (pupillometer) was basically the same as described above. Viewing conditions were monocular with the left eye occluded, and a second fixation cross was placed at the left periphery of the field for the right eye. Eye movement was always from the left peripheral to the central fixation cross, and angular distance of about eight degrees. A signal proportional to eye position was obtained by a previously described method¹². Test flashes were presented to the subject at various times before, during and after the beginning of a saccadic eye movement, and visual response (seen or unseen), pupillary response, eye movement and stimulus were recorded. A pulse with variable associated delay and constant width (10 msec) was used as the stimulus.

Pupillary responses to test flashes presented during and after the eye movement were averaged on a digital computer (GE 225) equipped with analog-to-digital converter¹⁴. For these stimuli the eye position signal served as a trigger both for the inputting sequence of the computer and for the presentation of the delayed test flash. The time of presentation of the test flash with respect to the beginning of the eye movement was determined by the delay setting. The subject indicated having seen a given test flash by depressing a push-button which caused a pulse to be registered on the recorder. Thus, visual saccadic suppression was followed on the recorder, while pupillary saccadic suppression was followed on the computer.

Responses to test flashes presented before the eye movement could not be averaged on the computer because: (1) the eye movement could not be used as an initiator; (2) the variability of the latency of eye movement was too great. In this case the subject moved his eye on receiving an auditory stimulus which also served as a trigger for the test flash. This was delayed so little that it occurred during the latency associated with the eye movement. These responses were grouped according to time of test flash presentation and hand-averaged. Saccadic suppression was followed as already described here.

Average responses to test flashes presented during and after the eye movement are shown in Fig. 2. Pupillary responses are shown in arbitrary units. Controls consisted of: curve *A*, responses to the test flash during central fixation, that is, with no eye movement; curve *B*, responses to the test flash during left peripheral fixation (no eye movement); curve *C*, responses to the eye movement with no test flash presentation. In some experiments a small pupillary response was observed in this last control, probably due to a small change in accommodation from one fixation point to the next. The average response for this control was subtracted from all computer-averaged responses (excepting controls) in order to emphasize more clearly trends in the data. Curves *D-L* represent average responses to these test flashes (control *C* subtracted out), the time of flash presentation with respect to the beginning of the eye movement appearing to the right of each response. It is clear that the average pupillary response is much diminished for short times of flash presentation. As the time of flash presentation approaches 980 msec the average response amplitude approaches that of the control responses. Fig. 3 shows psychophysical saccadic suppression and pupillary saccadic suppression results from the same experiments where test

Fig. 2. Pupillary responses to test flashes presented at various times during and after eye movement. Time of presentation in msec appears at right of each average response. Curves A, B and C are controls

flashes were presented before, during and after the eye movement. The visual saccadic suppression observed in this experiment agrees in general with previously published results^{7,12}. When saccadic suppression is maximal no test flashes are seen and the average pupillary response is reduced to 10 per cent of the average response to the test flash during central fixation. While it is clear that visual and pupillary saccadic suppression occur concurrently, the time-course of pupillary saccadic suppression seems far more extensive than that of visual saccadic suppression. This experiment has been performed on

Fig. 3. Saccadic suppression and pupillary saccadic suppression as a function of time of flash presentation with respect to beginning of eye movement ($t=0$). Visual response represents per cent seen; pupil response represents average amplitude as percentage of amplitude of average response during central fixation

two subjects and the results are quite similar for both.

Much of the pupillary saccadic suppression observed in these experiments occurs before the eye movement, seemingly minimizing the probability that the suppression is caused by an artefact. Possibilities for such artefacts are non-linear addition in the pupillary system¹⁵⁻¹⁷ and illumination of new retinal areas caused by the eye movement.

Based on the results of these experiments we are not able to determine whether the suppression observed in binocular rivalry and that observed in saccadic suppression are generated by the same mechanism. It is hoped that further experiments, both neurophysiological and psychophysical, will further elucidate these as well as many other related phenomena.

FUNCTIONAL SIGNIFICANCE OF SWEAT GLANDS AND SEBACEOUS GLANDS IN SEALS

By JOHN K. LING

Antarctic Division, Department of External Affairs, Melbourne, Australia

BIOLOGICAL investigations being carried out by Australian National Antarctic Research Expeditions at Macquarie Island (54° 30' S., 159° E.) include a study of the skin and hair cycle of the southern elephant seal, *Mirounga leonina* (L.)¹. Skin samples have been collected from five other pinnipeds also inhabiting southern latitudes but from different climatic regions.

It has been regarded as typical among mammals for the apocrine sweat glands to open into the pilary canal above the opening of the sebaceous glands, or even on to the skin surface². In the Phocidae this situation is reversed (Fig. 1), as previously noted in reports on skin from the general body surface³⁻⁵. Examination of serial sections of skin cut parallel to the skin surface of the

Fig. 1. Section of elephant seal skin from back, cut parallel to hair follicles to show opening, *SbO*, of sebaceous duct, *SbD*, above orifice, *SwO*, of sweat duct, *SwD*. *SbG* = sebaceous gland; *Sc* = stratum corneum. Oil red O and haemalum. $\times 27.5$

body and flippers of three phocid species confirms that the sweat ducts enter the hair canal below the sebaceous gland ducts.

Sweat glands in the Otariidae open into the pilary canal above the sebaceous gland openings over the general body surface (Fig. 2A). It is remarkable, however, that the apocrine sweat glands associated with hair groups on the flippers of the Australian fur seal, *Arctocephalus doriferus* Wood Jones, enter the pilary canal by way of a duct opening below the sebaceous gland orifice (Fig. 2B). Thus we have opposite arrangements on different parts of the same species of seal. The distally naked areas of skin on the fore and hind flippers have no cutaneous glands, although sections of 'naked' regions on hind flippers of the New Zealand fur seal, *Arctocephalus forsteri* (Lesson), have revealed minute hairs with asso-

ciated sweat and sebaceous glands. These hairs could not be seen when the outer surface of fixed material was viewed microscopically.

In the true seals (Phocidae) the sweat glands are rather insignificant, though in accurately oriented longitudinal sections their ducts can generally be traced alongside the follicle and seen to open just above the constricted region. Thus the sweat duct passes between the sebaceous gland and the follicle, and the two gland openings are visible one above the other, with the mouth of the sebaceous duct appearing in the form of a delta among the lamellae of the stratum corneum, particularly of the elephant seal. Copious lipid secretion can be demonstrated in frozen sections stained with oil red O (Fig. 1).

The sweat glands over the general body surface of the fur seals (Otariidae) are relatively enormous organs extending well below the bases of the hair follicles. Their secretory portions are much coiled and the ducts ascend outside the sebaceous glands to open into the funnel-shaped upper end of the pilary canal above the sebaceous gland opening. On the hairy proximal regions of the flippers of otariids the sweat glands are somewhat reduced and their ducts ascend between the follicle and the sebaceous gland in the same way as on all regions of phocids. In these areas the sebaceous glands are larger and the stratum corneum is thicker and more richly supplied with lipids.

The bilobed sebaceous glands of Phocidae are large compared with the size of the follicle and are situated on its ental side. These glands have unequal lobes in the Otariidae and the larger one enters the ental side of the guard hair follicle, while the smaller and more slender duct opens on the ectal side of the underfur follicles that emerge from a common pilary canal.

With the exception of the harp seal, *Pagophilus groenlandicus* (Erxleben), the relative positions of the cutaneous gland openings on the general body surface are distinct for the two families of seals. Bergersen's³ meticulous observations on *P. groenlandicus* leave no doubt that the sweat gland orifice in this species lies above the opening of the sebaceous glands. However, in addition to the guard hair, the follicle bundles of the harp seal contain 5-9 subsidiary hairs, quite a high number in comparison with other phocid species.

It has been stated that the naked areas of flippers of all Pinnipedia—including the walrus, *Odobenus rosmarus* (L.)—are devoid of sweat glands⁴. However, the appearance of liquid droplets on the glabrous palmar surface of the northern fur seal, *Calorhinus ursinus* (L.), after exposure to radiant heat was assumed to indicate that sweating had been induced⁵. Large and abundant sweat glands have been found in microscopic preparations of skin from naked regions of fore and hind flippers of the same species⁷.

I recently noticed fine hairs with associated cutaneous glands in histological sections of apparently naked skin from the fore flipper of *C. ursinus* (kindly lent by Dr. V. B. Scheffer). A similar situation obtains in the 'naked' skin of the hind flipper (but not the fore flipper) of *A. forsteri*. No cutaneous appendages have been found in naked skin of the fore or hind flippers of other southern otariids. There were, however, delicate, lipid-rich strands ascending vertically through the stratum corneum on the hairless part of the fore flipper of the Kerguelen fur seal, *Arctocephalus tropicalis gazella* (Peters), but no associated tubules were visible in the dermis. The nature of these structures remains unknown.

The phylogenetic significance of apocrine sweat glands in primates has been discussed recently in terms of the shifting position of the orifice of the sweat duct from the skin surface of the Erosimii to within the pilary canal of man². This latter situation is common for most mammals, an exception being the pig, the glands of which open on to the skin surface⁸. Thus there is no clear relationship between the amount of hair and the position of the sweat gland orifice in mammals described so far.

Fig. 2. Sections of Australian fur seal skin cut parallel to hair follicles showing relative positions of cutaneous gland openings into pilary canal. *SwG* = sweat gland. Other lettering as for Fig. 1. A, Dorsal body surface, $\times 54$. B, Dorsal surface of hind flipper. Mallory's triple stain $\times 64.5$

The morphology of sebaceous and sweat glands in seals may be related to the adaptation of these animals to their aquatic environment. Loss of functional hair in the thermoregulatory sense among the Phocidae and on the flippers of the Otariidae was accompanied (or followed?) by reduction in size of the sweat glands and a shifting of their excretory pore to a position below that of the sebaceous gland opening. Sebaceous glands are relatively larger in the skin of sparsely haired phocids and on less hairy parts of otariids, and these glands secrete a heavy lipid deposit within the stratum corneum. Although the sweat glands of the walrus—an almost hairless pinniped—are large, they actually atrophy during autumn⁹. The sebaceous glands are relatively small, but the nature of their secretion is not known.

Aoki and Wada¹⁰ have shown that sweat glands on the general body surface of dogs are sensitive to local stimuli such as radiant heat and drugs, but are insensitive to bodily conditions of heat stress. These authors suggested that temperature regulation is the chief function of the apocrine sweat glands of dogs. It is probable that similar local effects of sweat glands are associated with the hair bundles of heavily furred body regions of fur seals and the harp seal.

There is an apparent distinction in relative size and position of the sweat glands and sebaceous glands between the more terrestrially inclined Otariidae and the aquatically adapted Phocidae. This seems to weaken the argument for a biphyletic origin of the Pinnipedia¹¹. Sweat glands appear to be functionally important in association

with an elaborate pelage where their role is probably the regulation of local skin temperature. With the progressive loss of hair, exemplified by seals of the family Phocidae, the need for water-proofing the skin is met by enlarged lipid-secreting sebaceous glands, thermoregulation being achieved by the thick layer of subcutaneous blubber. It has been suggested that northern fur seals depend on their naked flippers for maintenance of their body temperature⁷, but this may not be a general rule in the Otariidae. The density, size and distribution of cutaneous glands, if any, and blood vessels in the naked flippers of Otariidae need to be carefully analysed before their significance can be evaluated.

Further detailed quantitative studies of the skin of pinnipeds and other aquatic mammals are required to elucidate structure and function of the integument and its associated glands. Perhaps the evolutionary path back to the water by these once terrestrial forms will then emerge.

INTERFEROMETRIC ESTIMATION OF EFFECTS OF TESTOSTERONE AND METHANDROSTENOLONE ON THE DRY MASS OF VARIOUS RAT MUSCLES

By DR. W. STAÜBLI and DR. T. OKADA

Research Laboratories, Pharmaceutical Department, Ciba, Ltd., Basle

IN animals following castration certain target organs display marked atrophy, which is reflected in a decrease in their wet and dry weights¹. This loss of weight of hormone-dependent organs can be partly or completely reversed by giving the castrated animals substitution treatment with androgenic¹⁻³ or anabolic² steroid hormones. In the present study we investigated the myotrophic effect of testosterone and methandrostenolone ('Dianabol') on certain skeletal muscles in the castrated rat. The optical path difference of the muscle fibres, as determined with the aid of an interference microscope, was selected as a criterion of the effect exerted by the hormones on the muscles.

Male Sprague-Dawley rats weighing approximately 100 g were used. They were kept on a standardized diet, and offered drinking-water *ad lib*. The rats were divided as follows into four groups, each containing four animals: (1) untreated controls; (2) castrated controls; (3) castrated animals, given one subcutaneous injection of testosterone (10 mg/kg in sesame oil) daily for 14 days, starting on the 15th day after castration; (4) castrated animals, given one subcutaneous injection of methandrostenolone (30 mg/kg in sesame oil) daily for 14 days, starting on the 15th day after castration. The m. levator ani and the m. bulbocavernosus were selected as representative 'sexual muscles'. Since the m. levator ani displays the characteristic features of a 'white' muscle⁴, the white portion of the m. psoas was used for comparison purposes.

Immediately after removal, the muscle tissue was fixed in Carnoy's solution, mounted in paraffin, and 4 μ sections were prepared. For the purposes of interfero-

metry, the sections, after removal of the paraffin, were covered with glycerol.

The optical path difference of the muscle fibres (φ) was estimated on longitudinal sections of the fibres (Fig. 1) with the aid of a Leitz interference microscope (fluorite objective with a magnification of 50 times, A , 0.85; monochromatic light of $\lambda = 546$ m μ) by measuring the displacement of the interference bands (d/D , Fig. 1) caused by the object. The optical path difference determined in this way is in direct proportion to the dry mass per unit of area⁵ (A_1 , A_2 , A_3 , Fig. 1). As the volumes (V_1 , V_2 , V_3 , Fig. 1) of the muscle fibres fluctuated markedly in response to hormonal treatment (Fig. 1), the following volume parameters were determined on photographs of cross-sections stained with haematoxylin-eosin: (1) the number of muscle cell nuclei per unit of area (5 cm \times 5 cm); (2) the number of muscle fibres per unit of area; (3) the area of the muscle fibres as estimated by planimetry (A'_1 , A'_2 , A'_3). Since the thickness of the specimens (t , Fig. 1) was kept constant, the path difference can be regarded as proportional⁶ to the concentration of

substances ($C = \frac{M}{V}$) in the muscle fibres. The volume

V is a prism, the sides of which are marked a , l (length of the muscle fibre), and t (thickness of the section) in Fig. 1.

After the wet weight had been measured, the muscles were dried to constant weight at 110° C for the purpose of estimating their dry weight.

It is known that the areas of the fibre cross-sections in certain target muscles are considerably reduced as a result of castration⁶. Since the muscle fibres in histological

† This value is significantly ($P < 0.01$) higher than the corresponding value of untreated controls.

cross-sections usually have an irregular polygonal configuration, measurement of their diameter is not a suitable criterion for estimating changes in their volume. The dependence of the 3-volume parameters already mentioned on the hormonal treatment is shown in Table 1. As was to be expected⁴, castration led to a reduction in the volume of the muscle fibres, which was reflected in an increase in the number of cell nuclei and of muscle fibres per unit of area and in a decrease in the areas of the fibre cross-sections. The extent of this reduction in volume was most marked in the case of the m. bulbocavernosus, less marked in that of the m. levator ani, and least marked of all in that of the m. psoas.

The administration of testosterone and of methandrostenolone to castrated animals in the dosages indicated produced an increase in fibre volume in all the types of muscle studied (cf. Fig. 1); the reaction of these muscles to the hormonal stimulus, however, was not uniform. Thus, testosterone and methandrostenolone increased the fibre volume in the m. levator ani and in the m. psoas almost to the level of that in the untreated controls, whereas the values for the m. bulbocavernosus were lower. Both testosterone and, to a somewhat lesser extent, methandrostenolone caused the fibre volume of the m. levator ani, as estimated by measuring the area of the fibre cross-sections, to rise above the control-levels by 9 and 7 per cent respectively (Table 1).

The results of the interferometric estimation of the optical path difference are indicated in Table 2. It can be

Table 2. DEPENDENCE OF THE OPTICAL PATH DIFFERENCE (f) ON HORMONAL TREATMENT

Treatment	(Mean values \pm S.E.)		
	M. levator ani	M. bulbocavernosus	M. psoas (white)
Untreated controls	0.37 ± 0.032	0.36 ± 0.054	0.35 ± 0.039
Castrated controls	$0.49 \pm 0.088^*$	0.39 ± 0.143	$0.45 \pm 0.06^*$
Testosterone	0.39 ± 0.084	0.40 ± 0.141	0.41 ± 0.140
Methandrostenolone	0.33 ± 0.156	0.39 ± 0.079	0.36 ± 0.075

* These values differ significantly ($P < 0.01$) from those of the corresponding untreated controls.

seen that castration caused a slight increase in the optical path difference and thus in the dry weight/area of the muscle fibres (cf. Fig. 1). The administration of testosterone or methandrostenolone brings the optical path difference back again to within the vicinity of the control-levels.

The castration-induced increase in the optical path difference of muscle fibres appeared to be relatively small (Fig. 1). Since the area (A_2) of the fibres is markedly reduced following castration, the optical path difference

$\varphi (= \frac{M_2}{A_2})$ would have to show a corresponding increase

in relation to the untreated controls if the dry mass remains constant ($M_1 = M_2$). As, however, this is not the case (Table 2), it can be assumed that the muscle fibres must undergo an appreciable loss of substance as a result of castration and that the two hormones are capable of making good this loss (Fig. 1 and Table 2).

This loss of substance, demonstrated with the aid of interferometry, must also exert an effect on the concentration of dry substances in the muscle fibres. Since the considerable diminution in the volumes (Table 1), which occurs following castration, is accompanied by a loss of dry mass, the concentration in the muscle fibres of castrated animals does not undergo any substantial change in comparison with the untreated controls and the hormone-treated animals (Fig. 1). In the light of the proportional relationship between the optical path difference and the concentration⁵ in our experimental procedure, we attempted to correct the path difference with the aid of the volume parameters listed in Table 1 (Table 3). It can be seen that the following expressions yield values which—

Table 3. RELATIONSHIP BETWEEN THE CORRECTED OPTICAL PATH DIFFERENCE AND DRY WEIGHT (AS DETERMINED GRAVIMETRICALLY)

Muscle	Treatment	As percentage of untreated controls			
		$\varphi^*/(1a)$	$\varphi/(2a)$	$\varphi x(3a)$	Dry weight
M. levator ani	Castrated controls	44	31	35	38
	Testosterone	92	130	115	98
	Methandrostenolone	80	115	96	96
M. bulbocavernosus	Castrated controls	32	17	16	16
	Testosterone	86	79	84	86
	Methandrostenolone	86	83	86	88
M. psoas (white)	Castrated controls	68	69	77	—

	Methandrostenolone	115	123	99	—

* φ (compare with Table 2) was corrected with the aid of the volume parameters listed in Table 1.

Dry weight W	$W_1 \gg W_2 \ll W_3 (\approx W_1)$
Area A (longitudinal section)	$A_1 \gg A_2 \ll A_3 (\approx A_1)$
Volume V (a-l-t)	$V_1 \gg V_2 \ll V_3 (\approx V_1)$ (Table 1)
Concentration $C = \frac{M}{V}$	$C_1 \approx C_2 \approx C_3$
Optical path difference φ	$\varphi_1 \approx \varphi_2 \approx \varphi_3$ (Table 2)
Dry mass $\frac{M}{A} = \varphi$	$M_1 \approx M_2 \approx M_3$
Dry mass $M = \varphi \cdot A$	$M_1 \gg M_2 \ll M_3$

Fig. 1. Diagram showing the experimental procedure

with a few exceptions to be dealt with later—tally reasonably well with the gravimetric estimation of the dry weight (Table 3): (1) ratio between optical path difference (φ) and number of cell nuclei per unit of area (1a, 4a, 7a, Table 1); (2) ratio between optical path difference (φ) and number of fibres per unit of area (2a, 5a, 8a, Table 1); (3) product of optical path difference (φ) and area of the fibre cross-sections (3a, 6a, 9a, Table 1). Among the various volume parameters, the optical path difference (expressed in terms of concentration of dry substance) appeared to be most directly related to the area of the fibre cross-sections.

Table 3 also shows that following testosterone treatment the corrected optical path difference (column 3b) of the m. levator ani and of the m. psoas is 15 and 19 per cent, respectively, above the corresponding values in the untreated controls; methandrostenolone does not display this effect.

The reason for this difference is not known. There are, however, two main possibilities:

(1) It is conceivable⁷ that the hormone-stimulated synthesis of cellular substances, that is, contractile proteins, for example, proceeds more rapidly in the region of the cell nuclei at the periphery than in those zones of the fibres further removed from the nuclei. Hence, there would have to be a concentration gradient decreasing from the periphery towards the centre of the fibre. The optical path difference, however, was determined at the periphery of the fibre. If this gradient were to be maintained for longer following testosterone than following methandrostenolone, determination of the optical path difference should yield higher values for testosterone. The figures listed in Table 2 do in fact indicate that testosterone tends to raise the optical path difference in the 'white' muscles

above the values found for methandrostenolone. Pointing in the same direction is the observation that following testosterone an inhomogeneous distribution of the myofibrils is encountered in stained histological cross-sections of the m. levator ani and m. psoas; this cytological picture could be due to the fact that hormonal stimulation of the sarcoplasm and its particulate organelles⁸ has not yet been completely arrested² at this point (14 days after castration).

(2) The second possible explanation would be that determination of the optical path difference yields higher values following testosterone than following methandrostenolone (Table 2) because the dry mass of connective tissue (*D*, Fig. 1) is affected in different ways by the hormones which nevertheless otherwise exert the same type of effect on the muscle cell.

The results of interferometric measurements of individual muscle fibres are very closely related to those of gravimetric determinations of muscle mass. Although the interferometric method is rather laborious, it makes it possible to quantitate certain cytological changes which may be encountered as a result of hormone treatment.

We thank Prof. F. Ruch of the Federal Institute of Technology, Zurich, for his advice and Dr. P. Barthe for his help in preparing the animals for the experiments.

A PHAGOCYTIC FUNCTION OF HASSALL'S CORPUSCLES

By Dr. J. N. BLAU

Pathology Department, Guy's Hospital Medical School, London, S.E.1

IN *The Microscopic Anatomy of the Human Body in Health and Disease*, published in 1849, Hassall¹ first described and illustrated the corpuscles which bear his name. He quotes from a 'Prize Essay' entitled *A Physiological Essay on the Thymus Gland* by John Simon, F.R.S. (Renshaw, London, 1845), who examined thymus glands from animals of varying maturity and concluded from "the application of acetic acid to the histological section", that the cells of the corpuscles had a "great affinity to embryonic cells". The origin and function of these corpuscles remain unknown or under dispute, and as recently as 1964 Christianna Smith², an authority on thymic anatomy, wrote: "The weight of evidence as to the origin of typical Hassall's corpuscles favours the theory stated by Kingsbury in 1928, that they are the expression of growth within a confined space of an epithelium which has lost its surface function not dissimilar to the epithelial pearls of keratinizing epitheliomas."

During an investigation of the entry of proteins, colloidal and particulate materials into the thymus of guinea-pigs under normal and pathological conditions, it was seen that Hassall's corpuscles were larger when the gland had involuted following either local X-irradiation or systemic cortisone. Two days after injecting indian ink into the circulation, particles of carbon were visible in macrophages inside the thymus of control animals and in greater concentration in the treated group. In addition, carbon was evident in some Hassall's corpuscles, and it is this phenomenon that is the special purpose of this article.

Young immature albino guinea-pigs (Hartley strain) of both sexes, weighing 220–370 g and 7–10 weeks old, were

grouped into animals of comparable weight and sex. Each experimental animal had its own control. The thymus was caused to involute either by local X-irradiation or by systemic injection of cortisone.

Each animal was anaesthetized with intraperitoneal Standard Veterinary Pentobarbitone Sodium B.P. (Abbotts), laid on its back and the limbs secured. A lead screen covered the animal apart from a window, 4 cm × 5 cm, through which 300 r. of X-rays were directed to the ventral aspect of the neck. The irradiation constants were 40 r./min, 220 kV and half-value layer 1.4 mm copper. Five animals were irradiated, three of which were allowed to survive for 2 days and two for 7 days when they were killed. Five control animals were anaesthetized, not irradiated and killed at similar time-intervals. In the cortisone group, five animals received subcutaneous injections of cortisone acetate B.P. (Organon) twice daily; two had 2.5 mg for 5 days and three others had 5.0 mg for 7 days after which time they were killed. Five control animals had the same number of subcutaneous injections of sterile saline in the same volume, 0.1 and 0.2 ml.

Each animal, irradiated, cortisone treated or control, had one intracardiac injection of 0.1–0.15 ml./100 g body-weight of indian ink (Günther Wagner Pelikan Werke, Hanover, Batch C11/1431a), which consisted of 10 per cent carbon black with an average particle size of 290–500 Å, stabilized with 4.3 per cent fish glue, and contained 1 per cent phenol in water. The injections were given within 1 h of irradiation or at the commencement of the series of cortisone injections, with the exception of one

radiated animal and one control animal which were injected 2 days after the initial time and killed 1 h later.

The guinea-pig's thymus, which is situated in the neck, cannot be injured by intracardiac puncture.

The animals were killed with ether anaesthesia and the tissues immediately fixed in 10 per cent formal saline. Sections, 5-7 μ thick, were cut from each lobe of the thymus, a cervical and mesenteric lymph node, spleen and from either the lung or the liver. Sections stained with haematoxylin and eosin did not provide good contrast for the small carbon particles. For this purpose light staining with methylene blue or neutral red was better.

All the animals were seen to change to a slaty grey colour during the injection of indian ink, and to return to their normal colour within minutes. At post-mortem the spleen from each animal was intensely black and the liver darker than normal. Some lymph nodes were darkened in patches. The thymus glands from animals that had been exposed to X-rays or treated with cortisone were darker than those from control animals which were pink. The treated group showed varying degrees of diminution in size of the thymus, and both groups had occasional black streaks on their surfaces.

Histologically, the spleen from each animal contained very large quantities of carbon in the sinuses of the organ. Large amounts of carbon particles were also to be seen in all the livers examined (irradiated group) and a considerable amount in the lungs (cortisone group). The lymph nodes, one cervical and one mesenteric from each animal, contained carbon particles albeit to varying extents.

After irradiation, thymic lobules showed the 'inverted' relationship of cortex to medulla, the cortex staining less deeply owing to impoverishment of thymocytes and prominence of reticulum cells. Following cortisone treatment the cortex was narrower than in control animals and showed the 'pockmarked' appearance. These cavities contained macrophages. The thymus glands from all treated animals contained a large number of Hassall's corpuscles, their size at times reaching very large dimensions.

Particles of carbon were evident in blood-vessel walls inside the gland as well as between and on the surface of lobules. The uniformly small particles in the wall of blood vessels contrasted with their size in macrophages where they ranged from small to large and in many instances had aggregated into sizable masses (Figs. 1 and 3). These heavily laden macrophages were to be found in the capsule, cortex, cortico-medullary junction and the medulla. In the cortex they frequently occupied the

Fig. 1. Blood vessel at cortico-medullary junction from an animal treated with 2.5 mg cortisone twice daily for 5 days showing carbon in macrophages inside dilated vessel. Fine particles of carbon are seen in vessel wall and larger aggregates in macrophages adjacent to and away from the vessel (methylene blue, $\times 540$).

Fig. 2. Hassall's corpuscle containing carbon particles of varying sizes. Animal irradiated with 300 r locally over the thymus and indian ink injected intravascularly 7 days previously. Carbon particles, indicated by arrows, have to be distinguished from deeply staining nuclear debris (methylene blue, $\times 540$).

Fig. 3. From same animals as Fig. 2, showing the appearance of a 'compound' Hassall's corpuscle containing carbon. A heavily laden perivascular macrophage and 3 other macrophages not proximate to a vessel are visible (methylene blue, $\times 540$).

cavities of the 'pockmarking'. At the cortico-medullary junction where the blood vessels were dilated they were situated perivascularly. In the medulla some were close to, and others well away from, blood vessels. The concentration of carbon-bearing macrophages at the junction of the cortex and medulla was striking in some cortisone-treated animals and contrasted with the occurrence, often in patches, of solitary labelled macrophages both in the cortex and medulla in the irradiated group. In all the treated animals the quantity of carbon was much greater than in control groups, and comparison of the whole series showed that, the longer the time that had elapsed between injection of indian ink and death, the more carbon was present in the gland.

The Hassall's corpuscles consisted of a hyaline lamellated portion resembling a cut onion. Associated with this was a variable amount of deeply staining chromatin material consisting of small nuclear fragments, their differing shapes resembling polymorphonuclear leucocytes. In control animals this 'compound' corpuscle occurred far less frequently and was invariably smaller than in involuted glands. There they gave the appearance of having resulted from the fusion of two and often more corpuscles and were very large (Fig. 3).

Fig. 4. Hassall's corpuscle from an animal injected with 5 mg cortisone twice daily for 7 days. Carbon is seen outside, at the edge and inside the corpuscle (methylene blue, $\times 540$)

Carbon was rare in the lamellated portion of the corpuscle, but was evident in varying quantities and size of particle among the nuclear debris (Fig. 4). By no means did all the corpuscles in stimulated animals contain carbon, yet some control animals had a few of these 'compound' corpuscles which contained a little carbon, suggesting that involution was going on. At the periphery of a corpuscle a large cell with foamy cytoplasm was seen at times to contain one or more particles of carbon. Here as well as inside the corpuscle the variable size of the particulate matter corresponded to the variation found in macrophages (Fig. 4).

The striking morphological resemblance of Hassall's corpuscles to keratinized squamous epithelium has perhaps been one of the mainstays of the belief that they are vestigial remnants arising from epidermal invagination from the third and fourth branchial pouches. The human embryos on which Norris³ based his conclusions were examined by Ruth *et al.*⁴ in the Embryology Department of the Carnegie Institute, Washington. The latter stated that: "Norris is the only investigator who claims to have traced the development of these structures to ectoderm. His drawings are interesting but not convincing."

So far the views held on the origin of Hassall's corpuscles have obscured investigation of their potential active function. Thus, well-recognized observations of their increase in size following irradiation⁵ and systemic cortisone⁶ have been neglected. The increase in content of nuclear fragments noted in the corpuscles during involution of the thymus gland cannot be accounted for on the basis of an effete vestigial structure, neither can the presence of γ -globulin in the corpuscles of human infants, children⁷, normal adults and patients with myasthenia gravis⁸.

If Hassall's corpuscles are not vestigial structures, what then is their function? Kostowiecki⁹ argues that macrophages exist in the thymus and lists an impressive series of authors supporting his views. Green and Bloch¹⁰ showed that carbon particles appeared in macrophages in some new-born mice, Clark¹¹ confirmed the entry of ferritin in adult mice and Bailliff¹² found the thorotrast in the thymus of rats and mice. The experiments cited here, using carbon, confirm this in the guinea-pig, and other investigations with Evan's blue (unpublished) are also in agreement.

The suggestion that macrophages become incorporated and form Hassall's corpuscles has been made by Kostowiecki⁹, who found that following the intraperitoneal injection of Evan's blue the corpuscles were stained with dye. Clark¹¹, too, found this dye to be present in some cells which formed rudimentary corpuscles in mice.

The observations reported here demonstrated that particles of carbon are present in macrophages and in

Hassall's corpuscles if sufficient time is allowed to elapse after intravascular injection, and this effect was markedly accentuated if the gland was caused to involute. This function of the corpuscle has hitherto been hinted at, but not satisfactorily demonstrated for a number of possible reasons: use of the wrong animals, like rats and mice, where the corpuscles are rudimentary; use of normal animals in which the thymus gland is not involuting or involution is proceeding very slowly; failure to use a readily visible foreign particle; allowing insufficient time for the accumulation of foreign material in the gland. It is only the simultaneous presence of these four conditions which has made these observations possible. This may explain why in Marshall and White's experiments¹³ trypan blue and pneumococcal polysaccharide failed to enter the normal gland, yet gained entry when the gland was traumatized: hence their proposition of a blood-thymus barrier. Clark¹¹ supports the concept of a functional and partial barrier and the observations cited here would be in favour of such a barrier rather than an absolute one, since particulate matter, ferritin in mice and carbon in guinea-pigs, has been found in macrophages of unstimulated animals.

The mode of entry is almost certainly via the blood stream. In comparing sections from animals that had carbon injected 1 h, 2, 5 and 7 days before death, there were increasing quantities of particulate matter in macrophages situated perivascularly and well away from blood vessels. Hence a likely interpretation is that perivascular macrophages take up carbon from the walls of the blood vessels which they line, or possibly circulating macrophages migrate through these vessels, as is suggested by Fig. 1. The permeability of the small blood vessels of the thymus may well have been affected by irradiation and cortisone treatment, and certainly in the latter group vessels seemed more prominent. These perivascular macrophages might then migrate to the Hassall's corpuscles and contribute in their formation.

Whether this dynamic interpretation derived from a series of static histological sections, taken at timed intervals, is correct or not requires further evidence. However, if the definition of a reticulo-endothelial tissue is based on its ability to phagocytose foreign particulate matter, then the demonstration of carbon black inside Hassall's corpuscles must imply that they belong to this tissue system in the guinea-pig.

To what extent are these observations relevant to the behaviour of the thymus in man in health and disease? The illustrations of Hassall's corpuscles in children with involution of the thymus¹⁴ bear such close similarity to those seen in the guinea-pig after irradiation and systemic cortisone that one can see little, if any, difference. The presence of germinal centres in some patients with myasthenia gravis and in a strain of New Zealand mice¹⁵ implies that an antigenic stimulus has reached the organ. Furthermore, Marshall and White¹³ produced germinal centres in the guinea-pig thymus by direct injection of killed typhoid and paratyphoid bacilli into the exposed thymus gland. Hence it is possible that, if antigenic molecules reach the thymus via macrophages in sufficient concentration, this could provide the stimulus for the formation of germinal centres. The local conditions in the thymus which determine the formation of these centres awaits elucidation.

In conclusion, Hassall's corpuscles in the thymus glands of guinea-pigs have been shown to take up particles of carbon after the injection of indian ink into the circulation, especially when the thymus glands are undergoing involution caused either by X-irradiation or the systemic injection of cortisone. It is suggested that macrophages play an important part in the formation of Hassall's corpuscles which in certain circumstances have a phagocytic function and form a part of the reticulo-endothelial system.

ANDROGEN-OESTROGEN-INDUCED TUMOURS: LACTIC DEHYDROGENASE RELATIVE TO CHAETEPITHELIOMA INDUCTION IN THE SYRIAN HAMSTER

By PROF. F. T. ALGARD

Department of Biological Sciences, Victoria University, British Columbia, Canada

AND

A. H. DODGE and PROF. H. KIRKMAN

Department of Anatomy, Stanford University School of Medicine, California

THERE is some presumptive evidence that neoplastic changes (induction) and subsequent progression from the benign to the malignant state may be accompanied by fluctuations in enzyme patterns. In view, especially, of the accumulating data suggesting a possible relationship between lactic dehydrogenase (LDH) and progression in certain tumours¹, this enzyme has been selected for an initial study on the histogenesis and growth of an androgen-oestrogen-induced, hormone-dependent epithelioma (chaetepithelioma) deriving from matrix cells of hair follicles in the flank organs (scent glands) of the Syrian hamster².

The chaetepithelioma is a particularly favourable tumour for use in such an enzyme investigation because of the essential role of sex hormones in the clear-cut succession of developmental stages³. Under endogenous androgen influence the tumour arises from epithelial cells migrating from hair bulbs into adjacent connective tissue. These cells organize the connective tissue into microscopic, laminated, epithelial-connective tissue complexes (stage 1) which, under the influence of exogenous androgen stimulation, enlarge to barely macroscopic, still preneoplastic stage 2 nodules. Stage 2 masses enlarge and fuse to form potentially malignant stage 3 neoplasms only following the addition of oestrogen to the androgen².

Initially this survey of LDH has been limited to tumour-bearing animals treated with both the sex hormones required for progression to ultimate malignancy. Tissue samples were taken at appropriate intervals during the life-history of the neoplasm for isoenzyme histochemistry using microscopic methods as well as acrylamide-gel electrophoresis.

Each histological tissue sample was sectioned serially at 20 μ on an International Harris cryostat. Both fresh and acetone-fixed sections from each sample were incubated for 10–20 min in 0.1 M DL-lactate LDH medium. Since available sulphydryl (S-H) groups are known to reduce nitro-blue tetrazolium, fresh sections were incubated in the standard LDH medium containing the S-H blocking agent, *N*-ethyl-maleimide. Each of these procedures was controlled by omitting the substrate from the incubation medium. Definitive tumour tissue (stage 3) was subjected to electrophoresis on acrylamide-gel strips according to Brody⁴. Urea (2.6 M concentration) was used to depress the slowest migrating isoenzyme⁵ in tissue sections.

LDH assessments were made on three groups of androgen-oestrogen-treated animals selected after periods

of treatment known to evoke the different stages of tumorigenesis², that is, 100–175 days for stage 1, 150–250 days for stage 2, 250 days or longer for stage 3. Histologically, the flank organ hair matrices of the short-term androgen-oestrogen-treated animals contain variable amounts of LDH ranging from slight to relatively heavy concentrations. Smaller, though less-variable, amounts of LDH occur in the outer root sheaths of the hair bulbs. Connective tissue components (dermal sheaths and papillae) always contain recognizable amounts. Laminated corpuscles (stage 1) contain recognizable quantities of LDH concentrated predominantly in the central core composed of epithelial cells. Little LDH is seen in the connective tissue laminae although scattered cells may contain as high a concentration as is present in any single cell in the central aggregate.

Stage 2 tumours, in which connective tissue components are reduced to a supporting stroma for cords of epithelial cells², contain greater concentrations of LDH than do stage 1 nodules, although considerable variation persists in different samples. With the transformation of stage 2 to stage 3 masses, the variability in amounts of LDH in different samples largely disappears and the concentration becomes distinctly greater.

Acrylamide-gel electrophoresis of stage 3 tumour tissue discloses four distinct bands of LDH. Of these, the most conspicuous is the slowest-moving isoenzyme, LDH No. 5 (ref. 4), with decreasing amounts of No. 4, No. 3 and No. 2. If the fastest-moving isoenzyme (No. 1) is present, its concentration is below the sensitivity threshold of this method. Attempts to isolate sufficient quantities of tissue from stages 1 and 2 for electrophoretic determinations have not yet been successful. These results are summarized in Figs. 1 and 2.

A 2.6 concentration of urea, which suppresses the slow-moving band (No. 5) (ref. 4) on acrylamide gel, is found in histological preparations to depress the LDH complement in the flank organ hair matrices, to completely inhibit the enzyme in stage 1 tumours, to depress the amount in stage 2 tumours to varying degrees and to diminish uniformly the reaction in stage 3 tumours. The order of magnitude of this latter inhibition is approximately 50 per cent which is roughly comparable to the percentage inhibition seen in the hair matrices.

It appears from this preliminary investigation that LDH diminishes during the initiation of stage 1 nodules, and that there is a gradual and variable synthesis of the

Fig. 1. Comparison of relative amount of LDH per section of the three tumour stages

enzyme, probably in more than one form, during the transformation of stage 1 to stage 2 masses and ultimately the marked elaboration of additional types and quantities of LDH during the development and growth of the definitive stage 3 tumour.

The full physiological significance of this investigation necessarily awaits the completion of similar studies of untreated males and females of varying ages, as well as animals treated independently with each of the two hormones. Of value, also, would be an investigation of the effect on types and levels of LDH in these tumours following hormone withdrawal. The correlation of hormone treatment with LDH synthesis during the life-history of this epithelioma may be physiologically significant, *in vivo*: whether there may be a direct influence on types and concentrations of LDH isoenzymes might, however, be best determined using *in vitro* techniques⁶⁻⁸. The possible

Fig. 2. Diagrammatic distribution of LDH isoenzymes in three tumour stages based on 2.6 urea inhibition investigations of sections and acrylamide-gel electrophoresis

involvement of viral LDH stimulating agents⁹⁻¹³ must await additional studies.

TITRATION CURVES DEPICTING CENTRAL STIMULANT, DEPRESSANT AND DUAL STIMULANT-DEPRESSANT ACTION OF GLUTARIMIDE HOMOLOGUES IN MICE

By DR. A. SHULMAN*, GLENDA M. LAYCOCK* and J. A. HENRY
Department of Physiology, University of Melbourne

EVIDENCE has been presented from quantitative titrations in mice that certain analeptics (including bemegride) and hypnotics (including pentobarbitone sodium) act at common sites in the central nervous system^{1,2}. It has been proposed³, in terms of 'rate theory' of drug action³, that with respect to the complex formed with the responsive sites, an analeptic is an agonist with high association and dissociation rate constants (k_1 and k_2 , respectively) and thereby maintains a continued high rate of association with the sites which manifests as convulsion. On the other hand, a hypnotic has a low k_2 and prevents the action of the agonist by its prolonged association with the responsive sites. Analepsis occurs when the agonist maintains a sufficiently high rate of

association in the presence of hypnotic to overcome the depression caused by the latter. The action of these drugs has also been described¹ in terms of 'receptor occupation theory' of drug action⁴.

Independent support for these views has been obtained from structure/action investigations in mice with members of a homologous series of β, β -disubstituted glutarimides. It has been shown that β -methyl- β -ethylglutarimide (bemegride, 'Megimide'), β -methyl- β -n-propylglutarimide and β -methyl- β -n-butylglutarimide and β -methyl- β -n-amylglutarimide show the properties of agonist, partial agonist and antagonists respectively in the central nervous system; the partial agonist, which is intermediate in structure between agonist and antagonist, has dual stimulant and depressant action and, it is proposed, an intermediate k_2 . It is probable that these substances

Table 1. MEDIAN CONVULSANT AND HYPNOTIC DOSES AND LEAST SQUARES REGRESSION LINES REPRESENTING TITRATION* BY PENTOBARBITONE SODIUM OF HOMOLOGOUS β,β -DIALKYLGLUTARIMIDES IN MICE

β,β -Di-alkyl glutarimide	Regression lines representing stimulant action	Regression lines representing depressant action	Median convulsant dose ($\mu\text{M/kg}$)	Median hypnotic dose ($\mu\text{M/kg}$)
Methyl, ethyl (bemegride)	$y = 0.2149x + 110.7$ (lower doses) $y = 0.0556x + 177.7$ (higher doses)	—	125.8 (123.0–137.6)†	—
Methyl, <i>n</i> -propyl	$y = 0.1027x + 112.9$ (lower doses)	$y = -0.0898x + 214.1$ (higher doses)	227.8 (227.1–228.5)†	2,232 (2,181–2,259)†
Methyl, <i>n</i> -butyl	—	$y = -0.0835x + 108.0$	—	1,840 (1,316–1,354)†
Methyl, <i>n</i> -amyl	—	$y = -0.1578x + 106.7$	—	676 (667–683)†

* The titration end-point is hypnosis in 50 per cent of a group of mice

† Estimated limits, $P = 0.05$

which differ only by the progressive addition of one methylene group to the β -alkyl substituent, and the hypnotic pentobarbitone sodium all act at common central sites which mediate both the stimulant and depressant actions of these drugs⁵.

If these views are correct, it may be anticipated that when progressively increasing doses of each of the aforementioned glutarimides are titrated against pentobarbitone sodium to an end-point of hypnosis in 50 per cent of a group of mice, the agonist will show only increasing analeptic activity, the partial agonist initial analeptic activity followed by potentiation of hypnosis, and the antagonist only increasing potentiation of hypnosis. Titration curves substantiating these views are shown in Fig. 1. In carrying out these titrations the titrants, either in aqueous solution (pentobarbitone sodium, bemegride and the *n*-propylglutarimide) or as a 1 per cent tragacanth suspension (the *n*-butyl- and *n*-amylglutarimides), were administered intraperitoneally in a temporal sequence such that their maximal effects occurred contemporaneously. The titration interval following drug administration was 10–15 min. Each titration point is the mean of at least two concordant estimations.

Theoretically, it is expected that the titration points for bemegride and its *n*-propyl homologue against pentobarbitone sodium take the form of hyperbolae⁶, but their relative analeptic potency has been estimated by fitting the points in each case by two highly significant least squares regression lines ($P < 0.001$) which intersect and show highly significant difference in slope ($P < 0.001$); each lower regression line intersects the hypnotic axis at a point non-significantly different from (0, HD_{50}) (Fig. 1 and Table 1).

It may be seen (Table 1) that bemegride is approximately twice as potent as its *n*-propyl homologue both as an analeptic to pentobarbitone sodium depression and as a convulsant. Their relative analeptic potency was calculated from the slopes of the lower regression lines, that is, where increasing doses of either glutarimide show

increasing antagonism to barbiturate depression, while their relative convulsive potency was calculated from the CD_{50} values (Table 1), estimated by plotting log. dosage of drug against probit percentage of mice which show mild clonic convulsion. By analogy with Paton's *in vitro* findings with homologous alkyltrimethylammonium cations⁷, it is likely that the k_1 values of bemegride and its *n*-propyl homologue are very similar and, hence, that the latter has a higher affinity (k_1/k_2) for the common responsive sites since, being a partial agonist, its k_2 is lower. It is also likely, judging by the close similarity in their structures and time courses of action, that a similar proportion of the peripheral dosages of the two glutarimides will reach the responsive sites during the titration interval. Consequently, it appears that k_2 of the drug-site complex is the cardinal factor determining the potency of these two drugs as stimulants in the central nervous system; this is to be expected from the assumption that k_2 limits the rate of dissociation of the drug from the responsive sites and hence its rate of association with the sites, and from Paton's definition of stimulant potency (k_2/k_1)⁸.

The inflexion in the bemegride–pentobarbitone sodium titration curve (Fig. 1) is considered to represent approaching saturation of the common sites for which the hypnotic has the greater affinity^{1,2}; a greater concentration of analeptic is required to attain the titration end-point in the presence of a hypnotic with a higher affinity when the drugs are present in excess with respect to the responsive sites than when the number of sites is adequate for maximal association of both drugs at the concentrations present. It is likely that the inflexion in the β -methyl- β -*n*-propylglutarimide–pentobarbitone sodium titration curve, in this case a change from a positive to a negative slope, also represents approaching saturation of the responsive sites since, in these circumstances, the stimulant action of the partial agonist would be expected to decline because its k_2 would be too low to permit the maintenance of an adequate rate of association when the number of free sites is limited.

The titration points of the *n*-butyl- and *n*-amylglutarimides against pentobarbitone sodium have also been fitted by least squares lines which show highly significant regression ($P < 0.001$) and which approximate very closely to the lines joining the estimated HD_{50} values of pentobarbitone sodium, 110.4 $\mu\text{M/kg}$ (109.2–111.0 $\mu\text{M/kg}$, $P = 0.05$), and β -methyl- β -*n*-butylglutarimide or β -methyl- β -*n*-amylglutarimide (Fig. 1 and Table 1). These HD_{50} values were estimated by plotting log dosage of drug against probit percentage of mice which lost righting reflex for at least 3 min.

Comparison of the slopes of the regression lines for the glutarimide hypnotics with that of the regression line for the higher doses of the partial agonist β -methyl- β -*n*-propylglutarimide shows that the *n*-amylglutarimide has approximately twice the depressant potency of its *n*-butyl homologue which is approximately equipotent to the *n*-propyl homologue (Table 1). However, the regression coefficient for the *n*-propylglutarimide gives a false

Fig. 1. Titration curves and least squares regression lines representing titration of pentobarbitone sodium by β -methyl- β -ethylglutarimide (Me,Et), β -methyl- β -*n*-propylglutarimide (Me,n-Pr), β -methyl- β -*n*-butylglutarimide (Me,n-Bu) and β -methyl- β -*n*-amylglutarimide (Me,n-Am). The titration end-point is hypnosis in 50 per cent of a group of mice. Each titration point is the mean of at least two concordant estimations

impression of its depressant potency since the regression line represents both decreasing anaesthesia, up to a dosage of 1,227 $\mu\text{M/kg}$, and potentiation of pentobarbitone-induced hypnosis at dosages beyond 1,227 $\mu\text{M/kg}$. A more accurate indication of the depressant potency of β -methyl- β -*n*-propylglutarimide is given by its HD_{50} , which was estimated by the same method already described here for the other glutarimides using a warm, near-saturated, aqueous solution (12 mg/ml.). A comparison of the HD_{50} values of the three glutarimides (Table 1) shows that β -methyl- β -*n*-amylglutarimide has approximately twice the depressant potency of its *n*-butyl homologue which is in turn approximately twice as potent as the *n*-propylglutarimide. This approximate two-fold difference in depressant potency for these drugs is similar to that shown for the stimulant potency of the ethyl and *n*-propyl homologues (Table 1) and probably reflects, primarily, a progressive fall in the k_2 of the drug-site complex representing, with each additional methylene group, the formation of a stronger bond between the glutarimide and the responsive sites.

It might be argued that potentiation of pentobarbitone sodium hypnosis by the higher doses of β -methyl- β -*n*-propylglutarimide results not from the action of the latter as a partial agonist but from its capacity to replace the barbiturate at common sites on plasma or tissue proteins or to decrease the rate of excretion, biotransformation or the extent of storage of the barbiturate, each of which would tend to increase the concentration of free hypnotic in the plasma for transfer to the responsive central sites. However, these possibilities seem unlikely since the *n*-propylglutarimide would need to be markedly more specific in these actions than its closely related ethyl, *n*-butyl and *n*-amyl homologues. The ethyl homologue, bemegride, is bound negligibly to plasma protein⁷ and shows continued anaesthetic activity against pentobarbitone sodium over a 117-fold range of anaesthetic dosage⁸, while the hypnotic *n*-butyl and *n*-amyl homologues produce no more than the expected additive depression in combination with the barbiturate.

Further, it has been demonstrated that whereas mice given β -methyl- β -*n*-propylglutarimide 500–600 $\mu\text{M/kg}$, in the absence of hypnotic, may die within 2–15 min of convulsion usually associated with maximal hindleg extensor tonus, animals receiving five times this dosage lose righting reflex within 2 min, following an initial burst of convulsion, and sleep without signs of stimulation for a period varying from 4 to 30 min. These mice wake with generalized hypertonia and excitement and show sporadic episodes of mild jumping and clonic movements the intensity of which decreases progressively until complete recovery some 3–4 h later. These observations suggest that β -methyl- β -*n*-propylglutarimide is a partial agonist which in high dosage can itself inhibit the maximal lethal convulsive action which it produces in a much lower dosage. Further, even though the drug is probably present for a considerable period at a concentration in excess of that necessary for maximal stimulation, it appears that the relationship between the k_1 and k_2 of the drug-site complex is such that the number of free responsive sites is never sufficiently high to maintain a rate of association greater than that commensurate with mild clonic convulsion.

Not only does β -methyl- β -*n*-propylglutarimide antagonize its own convulsant action but it also antagonizes that of its ethyl homologue (bemegride) and pentylenetetrazol. The *n*-propylglutarimide at a sub-hypnotic (1,800 $\mu\text{M/kg}$) or hypnotic dosage (Table 1) eliminates maximal hind-leg extensor tonus⁸ produced in mice by a 100 per cent effective intraperitoneal dosage of the ethyl homologue (290 $\mu\text{M/kg}$) or pentylenetetrazol (800 $\mu\text{M/kg}$); mice receiving 1,800 $\mu\text{M/kg}$ of the *n*-propylglutarimide show only mild stimulation and at times appear almost normal. Anticonvulsive action and potentiation of barbiturate depression by other compounds with stimulant properties

have been reported previously, for example, 5,5-diphenyl 2,4-diketooxazolidine and its hydantoin analogue ('Dilantin')⁹ and phenacyclidine and the related compound 'CI-581'¹⁰. Antagonism by high doses of stimulant action present in low doses has also been reported for the last-mentioned two compounds¹⁰.

As anticipated, β -methyl- β -*n*-propylglutarimide in low dosage (114 $\mu\text{M/kg}$, $0.5 \times CD_{50}$) potentiates the convulsive action of the ethyl homologue, decreasing its CD_{50} from 126.8 to 63.2 $\mu\text{M/kg}$ (62.7–63.7, $P = 0.05$); both drugs in a non-convulsive dosage ($0.5 \times CD_{50}$) are anaesthetic to the *n*-butyl and *n*-amyl homologues at their HD_{50} . On the other hand, a higher dosage of the *n*-propylglutarimide (1,800 $\mu\text{M/kg}$) potentiates the action of the HD_{50} of the hypnotic glutarimides.

The dual stimulant and depressant action of β -methyl- β -*n*-propylglutarimide and the form of its titration curve suggest that stimulation, manifesting as convulsion or anaesthesia, and depression, manifesting as anticonvulsive action and potentiation of hypnosis or hypnosis, are continuous phenomena. Thus, it is very likely that convulsion and hypnosis are the opposed extremes of a common physiological process occurring at the responsive central sites; the pure convulsive and hypnotic actions respectively of the ethyl and *n*-butyl homologues strongly support this contention. A hypothesis has been presented^{1,2} which suggests that convulsion and hypnosis produced by selected barbiturates, glutarimides and a variety of related drugs are the opposed extremes of physiological wakefulness occurring predominantly at excitatory synapses on reticular neurones concerned in arousal, and that anticonvulsive action is an intermediate state of depression. These views are consistent with those obtained from direct neurophysiological and neuropharmacological investigations¹¹ and with the ability of most anticonvulsive drugs to antagonize convulsion in low dosage and to produce hypnosis in higher dosage.

The relative affinities, association and dissociation rate constants and the central nervous system penetrabilities of pentobarbitone sodium, bemegride and other hypnotic and anaesthetic drugs¹ are being estimated (using the IBM 7044 computer) from titration curves of the type shown for bemegride and pentobarbitone sodium in Fig. 1 (ref. 6). These parameters, representing the action of the drugs at the common sites in the central nervous system of mice, will also be computed for the *n*-propyl, *n*-butyl, *n*-amyl and related glutarimide homologues from appropriate titration curves. It is hoped in this way to determine the progressive changes in the magnitudes of the association and dissociation rate constants which accompany the progressive addition of one methylene group to the β -alkyl substituent of the glutarimide ring. Similarly, changes in the penetrabilities of successive homologues can be examined and compared with changes in relevant physical characteristics.

It is suggested that the foregoing conclusions, concerning the central actions of β -methyl- β -*n*-propylglutarimide, and titrations of the type shown in Fig. 1 may be useful in elucidating the mode of action of other central nervous system stimulant and depressant drugs, especially those having apparently paradoxical actions. For example, these considerations have been applied to the central actions of a convulsant barbiturate and the anticonvulsant diphenylhydantoin sodium ('Dilantin'), and it seems possible that these substances, phenacyclidine and 'CI-581'¹⁰, a number of psychoactive drugs¹² and certain halogenated aliphatic ethers and paraffins¹³ also behave as partial agonists in the central nervous system and act at the same central sites common to the other drugs discussed in this article.

We thank Mr. R. Benn for his valuable assistance with the experiments and Nicholas Pty., Ltd., for their gift of the glutarimide drugs used in this investigation. This work was supported by the National Health and Medical Research Council of Australia.

BREEDING A PELAGIC COPEPOD, *Euterpina acutifrons* (Dana), IN THE LABORATORY

By HEINZ W. NEUNES and GIAN-FRANCO PONGOLINI

Laboratorio per lo Studio della Contaminazione Radioattiva del Mare, Comitato Nazionale per l'Energia Nucleare—European Atomic Energy Community, Fiascherino (La Spezia), Italy

IN order to evaluate the uptake, distribution and turnover of radioisotopes in a marine ecosystem, it is highly desirable to evaluate results observed in the open sea in terms of experiments carried out under precisely controlled conditions in the laboratory. An essential prerequisite is therefore to have at hand a method for rearing relevant organisms in the laboratory.

Copepods form an essential element in the marine food chains. So far, however, laboratory work with pelagic copepods has always posed serious problems, for it has been impossible to rear them under culture conditions which permit them to reproduce.

Only recently, Zillioux and Wilson¹ succeeded in maintaining a culture of the coastal species *Acartia tonsa* through five generations, and Conover² had previously been able to raise eggs of *Calanus hyperboreus* to the adult stage; these, however, failed to reproduce.

The excessive growth of bacteria in the culture vessels is presumed to be one of the main factors for the difficulties; Conover² therefore added antibiotics to the water. In order to bind heavy metal ions present, Bernhard³ used EDTA and other complexing agents and was thereby able to overcome the difficulties in culturing sea urchin larvae.

Taking advantage of this experience, we have carried out breeding experiments with some species of pelagic copepods, especially with *Temora stylifera*, *Oncaea* sp. and *Euterpina acutifrons*, which are abundant in the Mediterranean. The copepods came from the laboratory's sampling zone (see Bernhard *et al.*⁴) in the Ligurian Sea, about ten nautical miles off the coast near La Spezia; the samples were taken in surface tows over a water depth of about 250 m, except for the individuals of *Euterpina acutifrons*, used to set up the first laboratory culture, which originated from the Gulf of La Spezia in the immediate vicinity of the coast.

Aboard the ship, the plankton samples were diluted with natural sea-water and kept in 5-l. polyethylene bottles to which 50 mg/l. penicillin was added. The samples were then stored at 18° C. During the 20 min required to transport the plankton from the quay to the laboratory, no further precautions were taken to keep the temperature constant. Immediately on arrival, the copepods were transferred to culture vessels and kept in a room thermostatically controlled at 18° ± 1° C.

Natural sea-water served as basis for the culture media in all cases. EDTA in a concentration of 37 mg/l. (= 10⁻⁴ mol) was added as a complexing agent. As antibiotics, penicillin and streptomycin were used alternately; two different concentrations were tested: 50 mg/l. and 6.5

mg/l. The control media contained EDTA but no antibiotics.

A suspension of a mixture of the flagellates *Tetraselmis micropapillata*, *Dicrateria* sp. and *Platymonas* sp., a dinoflagellate *Gymnodinium* sp. and the diatom *Phaeodactylum tricornutum* was added as food. The culture medium was changed at regular intervals, using a siphon fitted with nylon gauze to prevent the nauplii from escaping; the intervals ranged from 1 week to 1 month according to the experiments.

The copepods were kept either individually as 'single cultures' in Boveri capsules with a capacity of 30 ml. or in groups of more than ten individuals as 'mass cultures' in Erlenmeyer flasks ranging in capacity from 2 l. to 10 l. The flasks were filled to half capacity or less.

In preliminary survival experiments with single cultures of *Temora stylifera* and *Oncaea* sp., two concentrations of antibiotics were compared: 6.5 mg/l. penicillin, in weekly alternation with 6.5 mg/l. streptomycin, gave better results than either the controls or the higher concentration of 50 mg/l. which was recommended by Conover².

The superiority of the lower concentration of antibiotics was significant at the 95 per cent level for *Temora* ($F = 3.73$ at *d.f.* 2 and 28). For *Oncaea*, although it also survived longer in the lower concentration, the difference was not statistically significant ($F = 1.71$ at *d.f.* 2 and 34). A mixture of various zooplankton species in a mass culture lived longer in the lower concentration of antibiotics than in the higher concentration and in the controls.

The original concentration of 50 mg/l. antibiotics appears to have some detrimental effect on the vitality of the copepods, which effect is reduced or eliminated by using a lower concentration. As to the effect of the penicillin medium on the bacteria, it should be kept in mind that an aqueous solution of penicillin is very unstable in sea-water. According to Korzybski and Kurylowicz⁵, a penicillin solution at pH 5 at 0° C loses about half its activity within 8 days; in weak alkaline solutions, such as sea-water (pH 8), and also at higher temperatures, the process of inactivation requires considerably less time.

In order to evaluate under these conditions the effect of a penicillin solution on the bacterial growth in copepod cultures, an experiment was set up in which periodic counts of bacteria were made.

Three different media were tested: (a) penicillin medium (6.5 mg/l. penicillin + 37 mg/l. EDTA), (b) sterilized sea-water (autoclaved for 20 min at 110° C, + EDTA), and (c) control medium (natural sea-water + EDTA). Two Boveri capsules were filled with each medium and five

Fig. 1. Bacterial growth in copepod cultures, set up with different media: —, natural sea-water; ---, penicillin solution (6.5 mg/l.);, sterilized sea-water. EDTA was included in all media

copepodites of *Euterpina acutifrons* added per capsule. The serial dilution method was used for the bacteriological tests; the diluted samples were then poured on "peptone agar" plates (Oppenheimer and ZoBell⁶) and the developing colonies were counted in due course. Samples for the bacteriological counts were taken from the cultures at 0, 14, 26, 38 and 62 h. The results are given in Fig. 1.

The results confirm that an appreciable difference in the number of bacteria can be noted in the first 38 h only. At zero time, the number of bacteria in the penicillin medium was 18 per cent of that of the controls, at 14 h about 40 per cent; after 26 h the numbers of bacteria in the penicillin medium and in the controls were about equal. In the sterilized medium which had been contaminated with bacteria by the copepods, the bacteria needed 62 h to reach the level of the controls. A parallel experiment with mass cultures of zooplankton showed a longer survival time in the penicillin medium, but shorter in sterilized sea-water.

The fact that the penicillin medium has a bacteriostatic effect during a period of less than a day may well be of vital importance, because it is possible that the resistance of copepods against excessive bacterial growth is extremely low during the initial period in which they are probably in a weakened condition after having undergone the straining procedures of collection, the transportation to the laboratory and finally the transfer by means of a pipette into the culture vessels.

The shorter survival-time in sterilized sea-water may be due to chemical changes effected by the high autoclaving temperature.

On the basis of these findings, the lower penicillin concentration (6.5 mg/l.) was adopted for standard culture medium.

The first species of which we obtained nauplii in the laboratory was *Euterpina acutifrons* (Dana), a pelagic copepod of the sub-order Harpacticoida. The nauplii, hatched from the eggs of females caught near the coast on August 22, 1963, were transferred into a bottle with 3 l. of standard culture medium. Initially, the medium was changed weekly. The population established itself but remained at a very low density. When, however, the medium was renewed at monthly intervals, the population

density increased rapidly. The population remained in the same vessel for one year. The masses of live and dead algae and detritus collecting at the bottom were never removed and did not have any obvious detrimental effect on the culture. In August 1964, the population was divided and distributed into several new containers.

The population was examined every 4 days over a period of several months. Young naupliar stages were always predominant, which suggests a rather high larval mortality.

Generally, the density was between 1,000 and 3,000 individuals per litre, with rather marked fluctuations. But high values such as the following have been observed: 500 adults, 2,000 copepodites, 2,500 nauplii IV-VI, 9,000 nauplii I-III. These numbers were calculated for 1 l. on the basis of replicate samples of 5 ml.

In order to determine the time required for the completion of one generation, the life history of single individuals was observed. Females with eggs were transferred from the laboratory population into Boveri capsules. On the following day, the nauplii which had hatched in the meantime were transferred singly into covered salt dishes containing about 3 ml. standard culture medium. Observations were made daily and the moulted skins were counted and removed. The mortality was high: only 22 out of 50 nauplii survived to the first copepodite stage and only two of those reached the adult stage. Another experiment was therefore set up with 50 nauplii of various stages taken directly from the laboratory population. Of these, 12 developed into adults. Table 1 gives a summary of the results, combining the two experiments. At 18° C the resulting average time for the completion of larval development (egg to adult) is between 17 and 18 days. This result is confirmed by another observation: in a population started anew with ten females bearing eggs, the first F_1 -adults appeared after 14 days and the first F_2 -nauplii after 17 days.

Table 1. DURATION OF LARVAL STAGES IN SINGLE CULTURES OF *Euterpina acutifrons* AT 18° C

	N	Length of larval period (days)						Overall av. (days)
		0	1	2	3	4	5	
Nauplius	I	57	44	12	1			1.3+0.5*
	II	38	23	14	1			1.4
	III	30	1	19	9	1		1.3
	IV	26		17	7	1	1	1.5
	V	16		18	8			1.5
	VI	23		22	1			1.0
Copepodite	I	23		11	10	2		1.6
	II	22		10	9	3		1.7
	III	22	1	8	6	6	1	1.9
	IV	20	1	7	11	1		1.6
	V	14		2	8	3	1	2.2
								Total 17.5

* To the mean time length of the naupliar stage I, 0.5 days were added, because at the time 0, the nauplii were between 0 and 24 h old.

This is not very different from records of other copepod species reared under similar conditions. The non-pelagic *Tigriopus brevicornis* needs 19.5 days on the average to grow from egg to adult (own observation), and *Acartia tonsa* has a generation time (egg to egg) of 21-30 days at 17° C (Zillioux and Wilson¹).

If we assume a period of about 3 days for the time between emergence as an adult and hatching of its first eggs, a generation of *Euterpina*, under the conditions described, averages 20-21 days. On the basis of this average, we can assume that the population, which is now 18 months old, at present should contain individuals which belong to the 27th generation.

Originally it was presumed that pelagic populations of *Euterpina* might be less resistant to culture conditions than the coastal one which was used to set up our first laboratory culture. Therefore, on November 28, 1963, and January 21, 1964, two new cultures were started with *Euterpina* collected in the open sea.

The resulting laboratory population performed just as well as the original one derived from a coastal population; there appeared to be no difference in their adaptability to culture conditions. One of the populations was later transferred to a culture medium without antibiotics with no apparent detrimental effects. It seems safe to assume that antibiotics are necessary only for the initiation of a laboratory culture.

It should be noted that *Euterpina acutifrons* is closely related to the non-pelagic genus *Tigriopus* which lives in tide pools and is very easy to maintain in the laboratory. It might be interesting to carry out culture experiments with other pelagic Harpacticoida as well, in order to determine whether a relatively high adaptability to culture conditions is a general feature of this group.

We thank Dr. U. Melchiorri-Santolini from our laboratory for his valuable help and advice in the bacteriological part of the work.

This work was carried out under association contract EURATOM-CNEN 024-63-BIAI.

OPTICAL ROTATORY DISPERSION OF A CHLOROPLAST PREPARATION

By Dr. BACON KE

Charles F. Kettering Research Laboratory, Yellow Springs, Ohio

OPTICAL rotatory dispersion (ORD) was used more than a century ago by Biot, Pasteur and others for the study of molecular structure¹. Its use on proteins dates back to the work of Hewitt² and Jessen-Hansen³ in 1927. During the interim period, rotation measurements have been limited in the main to a few wave-lengths where convenient light sources could be found. However, in the past decade ORD has been undergoing a renaissance, largely as a result of new applications it has found in the study of molecular structure, and it is now considered one of the most powerful methods for studying conformation and conformational changes in biological macromolecules.

The most significant use of ORD in protein work is probably the estimation of helix content of a protein and the detection of helix-coil transition taking place in proteins during denaturation. Another interesting area of molecular conformation studied by ORD is that found by Blout and Stryer⁴, who showed that Cotton effect can be induced in the absorption-band region of certain symmetrical dye molecules when they are complexed with a dissymmetric helical structure of a polypeptide. They also found that the Cotton effect reverses sign when the dye is bound to a polypeptide of an opposite helical sense. When the dye is bound to a polypeptide with random conformation, no Cotton effect is observed.

As ORD is sensitive to the conformation and conformational changes in proteins and to the effect of binding small molecules, we have investigated the rotatory properties of chlorophyll⁵ and other pigments in solution as well as in the native environment of the chloroplast, to gain some insight about the nature of binding of these pigments and to correlate it with the photosynthetic activity of the chloroplasts. This article presents some preliminary observations made on a chloroplast preparation.

The problem of binding of chlorophyll to lipoprotein has been investigated by many workers in the past, mainly through such optical properties as absorption and emission. Although the state of chlorophyll *in vivo* is probably radically different from that of isolated molecules in solution, the absorption peaks of the bound pigment usually display only a slight shift as a result of binding⁶. Studies of optical anisotropy have usually led to the conclusion of a textural or form anisotropy in the chloroplasts⁷⁻⁹. More recently, polarized-absorption and -emission measurements¹⁰ with *Euglena* chloroplasts and electric-dichroism measurements¹¹ with quantasomes have

indicated an orientation of part of the chlorophyll molecules in the chloroplasts.

Chloroplasts are known to be sites of photosynthesis. As revealed by electron microscopy, chloroplasts consist of laminated systems embedded in a matrix, or stroma. The lamellae and stroma are surrounded by a double membrane. The dark layers in the laminated system are where the chlorophylls and other pigments are concentrated. Considered chemically, the laminated system is a gigantic organized complex of lipoprotein and chromophores. However, the so-called chlorophyll-lipoprotein has never been isolated from the chloroplasts in pure form. When chloroplasts are broken, the dark regions are released in particulate forms called 'grana'. The lamellae appear to be made of sub-units which were first observed by Frey-Wyssling and Steinmann¹², and have recently been given the name of 'quantasomes'¹³. The quantasomes are oblate spheroids 200 × 100 Å. It has been suggested that the quantasomes probably represent the smallest functional units capable of carrying out quantum conversion and electron transport.

The chloroplasts used in this work were prepared from spinach leaves. Quantasome aggregates were prepared according to the procedure described by Park and Pon¹⁴, except that KCl was substituted for sucrose. Further rupture of the grana was achieved by sonication, and the lamellar fragments were fractionated and freed from stroma by differential centrifugation. ORD measurements were made in the Cary 'Model 60' spectropolarimeter, with cell compartments thermostatic at 24° C. Up to 600 mμ, the bandwidth was programmed at 3 mμ. Above 600 mμ, the bandwidth was manually set at 5 mμ to avoid excessive noise because of low light intensity.

ORD spectra of isolated chlorophylls *a* and *b* in diethyl ether over the visible and near ultra-violet regions have been reported recently⁵. Negative and positive Cotton effects were found to correspond to the major absorption bands in the red and blue regions, respectively. These Cotton effects indicate that the electronic transitions corresponding to the absorption bands are optically active. The Cotton-effect inflexion points correspond closely to the absorption peaks.

The ORD spectrum of the chloroplast suspension, shown in Fig. 1, shows considerably more complexity and intensity than that of the free chlorophylls. Cotton effects corresponding to almost all the absorption peaks of chlorophylls *a* and *b* are retained in the spectrum of the lipoprotein complex. For comparison, the ORD spectrum

Fig. 1. ORD spectra of a suspension of the chloroplast lamellar fragments (recording trace) and an ether solution of chlorophylls *a* and *b* (dashed line). Both solutions contain the same amount of chlorophylls *a* (15 $\mu\text{g/ml.}$) and *b* (5 $\mu\text{g/ml.}$). Arrows at top indicate absorption peaks of the chloroplast suspension; arrows at bottom indicate absorption peaks of the chlorophyll solution in ether. The scale bars represent a rotation of 0.01°.

of an ether solution containing equivalent amounts of isolated chlorophylls *a* and *b* is drawn in the same figure in dashed lines. The pigment absorption peaks of the chloroplast suspension and those of the free chlorophylls in ether in the visible region are indicated by arrows at the top and bottom of the spectra, respectively.

ORD measurements of mixtures of chlorophylls *a* and *b* at various proportions showed that the magnitude of rotation is apparently additive. Consequently, the Cotton effects of the chlorophyll mixture in the red region become less sharp. On the other hand, in the chloroplast suspension, the negative Cotton effects corresponding to chlorophyll *a* (678.5 $\text{m}\mu$) and chlorophyll *b* (650 $\text{m}\mu$) are completely resolved and their magnitude greatly enhanced. The positive Cotton effects corresponding to the two subsidiary bands of chlorophyll *a* (624 and 594 $\text{m}\mu$) in the chloroplasts are also discernible.

The Cotton effects of the free chlorophyll solution in the Soret region are much better resolved, apparently because of a greater magnitude of the effects and a wider separation of the absorption peaks. However, in the chloroplasts, because of overlapping absorption by the chlorophylls and carotenoids, the assignments of the Cotton effects to the individual adsorption peaks between 400 and 500 $\text{m}\mu$ becomes difficult. This is especially true for the overlapping absorption between chlorophyll *b* (470 $\text{m}\mu$) and the carotenoid band at 455 $\text{m}\mu$ and between chlorophyll *a* (437 $\text{m}\mu$) and another carotenoid band at 428 $\text{m}\mu$. Based on the known absorption-peak position of the carotenoids, the strong negative trough near 480 $\text{m}\mu$ was tentatively designated as a Cotton effect originating from the carotenoids.

A pronounced negative trough with peak wave-length at 235 $\text{m}\mu$ was observed in the chloroplast preparation. This is similar to the 233 $\text{m}\mu$ trough first observed by Simmons and Blout¹⁵ in the protein sub-units of tobacco mosaic virus and later in various other polypeptides and proteins¹, and is believed to represent the $n-\pi^*$ transition in the peptide chromophore. The magnitude of the 233 $\text{m}\mu$ trough has been used as an approximate measure of the α -helix content¹⁶ in a polypeptide or protein. By the same procedure of calculation¹⁶, and assuming the helical protein in the chloroplast lamellae to be a right-handed α -helix, the magnitude of the 'reduced mean residue rotation' corresponded to a helical content of the order of 15 per cent in the lamellar protein.

Our present knowledge about the nature of protein and lipids in the chloroplast lamellae is rather limited. Although the amino-acid composition of whole-leaf and chloroplastic proteins has been reported¹⁷, the amino-acid sequence and protein conformation remain to be determined. Several earlier studies^{9,18,19} reported the absence of ultra-violet dichroism in chloroplasts, and conse-

quently Goedheer⁹ and Ruch¹⁸ proposed that the chlorophyll molecules were complexed with spherical protein molecules and that the pigment molecules were only slightly oriented. However, drawing analogies from the lamellar structure in the para-crystalline phase of poly- γ -benzyl-L-glutamate¹⁹, it was suspected that chloroplast lamellae might also be composed of long parallel helices, with the pigment orientation governed by the available attachment sites. The low helical content found here was indeed contrary to expectation. However, the identification of the presence and the amount of α -helices in the chloroplast lamellae protein has lent a definitive character to the structural protein in the chloroplasts and furnished a conformational basis for any orientational effect on the pigments by the protein. There is no evidence that there might be a mixture of right- and left-handed helices present in the chloroplast lamellae. However, such a possibility should not be completely ruled out without further investigation.

The enhancement of the intrinsic Cotton effects of chlorophylls and carotenoids complexed with the lipoprotein suggests a strong interaction either between the pigment molecules themselves or between the pigment molecules and the attached macromolecules. The enhancement of rotation in the carotenoid absorption region appears to be especially strong. Although the xanthophylls present in spinach (the oxygen-containing derivatives of α -carotene) are known to be optically active, examination of a hexane extract containing ten times the combined carotenoid concentration of the chloroplast sample yielded only negligible rotation, mostly buried in the noise. The strong rotation in the carotenoid absorption region suggests a possibility of an orientational effect by the lipid matrix, resulting in either an induced Cotton effect in the carotenoids including the optically inactive β -carotene or an enhancement of rotation of the intrinsic optically active xanthophylls. Presumably the lipid matrix could also exert an orientational effect on the chlorophylls through the phytol chain. A definitive clarification to these suggestions obviously requires further investigation. ORD measurements appear to offer new avenues for such studies.

After the completion of this work, I learned the results of a similar study on quantasomes by K. Sauer²⁰. It has been found that isolated chlorophyll *a* at a high concentration in carbon tetrachloride exhibits profound changes in its ORD spectrum. Sauer attributed such enhancements to chlorophyll aggregation and felt that a similar pigment-pigment interaction could also account for the enhanced ORD spectrum observed in quantasomes.

LETTERS TO THE EDITOR

ASTROPHYSICS

Rotational Period of the Planet Mercury

In a recent communication by S. J. Peale and T. Gold¹ the rotational period of Mercury, determined from radar Doppler-spread measurements to be 59 ± 5 days², has been explained in terms of a solar tidal torque effect, taking into account the large eccentricity of Mercury's orbit, and the $1/r^6$ dependence of the tidal friction (r being the Sun-planet distance). They conclude from a very brief discussion that after slowing down from a higher direct angular velocity, the planet will have a final period of rotation between 56 and 88 days, depending on the assumed form of the dissipation function. However, from their discussion it is by no means clear why permanent deformations would imply a period of 88 days as a final rotation state after a slowing-down process. A very nearly uniform rotational motion of 58-65 sidereal-day period, that is $2/3$ of the orbital period, may indeed be a stable periodic solution. This rotational motion could have the axis of minimum moments of inertia nearly aligned with the Sun-Mercury radius vector at every perihelion passage. The orbital angular velocity at perihelion ($2\pi/56.6$ days) is close to $2\pi/58.65$ days, leading to an approximate alignment of the axis of minimum moment of inertia with the radius vector in an arc around perihelion where the interaction is strongest. The axial asymmetry of Mercury's inertia ellipsoid may result in a torque that counterbalances the tidal torque, giving a stable motion with this orientation and with a period two-thirds of the orbital period. It would therefore be possible for Mercury to have a higher permanent rigidity than that permitted by Peale and Gold.

In discussion with I. I. Shapiro³, we concluded that the actual rotational motion may have evolved via a speeding-up process from a lower angular velocity or possibly from a retrograde motion. We would point out that a 58-65-day period, precisely because it is $2/3$ of the orbital period, fits some of the old optical observations as well as the recent radar measurements.

Fig. 1

In Fig. 1 a rough planar sketch is shown of the orientation of Mercury's axis of minimum moment of inertia, at different points along its orbit, given that the rotational period is two-thirds of the orbital period and that this axis is aligned with the Sun-planet vector at perihelion.

ASTRONOMY

Filamentary Nebulosity in the Vicinity of the Cetus Arc

FORMING large diameter circles across the sky are three ridges of enhanced radio emission. They are the North Polar Spur¹, 111° in diameter, the Cetus Arc², 91° in diameter, and a third, unnamed, 60° diameter loop centred on the northern celestial pole³.

The radio continuum emission from these features is identical to that from the old supernova remnants. However, the nature of the 60° diameter loop is complicated by its correlation with twelve high-velocity neutral hydrogen clouds⁴. It has therefore been suggested that two, if not the third, of these objects are the remnants of nearby supernova explosions.

The principal difficulty to the acceptance of this theory has been the lack of detection of any optical emission regions coincident with these loops^{5,6}. All the accepted supernova remnants have characteristic filamentary nebulosity bounding their radio regions.

Such nebulosity has recently been searched for, on these three radio sources, in a photographic programme carried out at the high-altitude observatories of Jungfraujoch and Pic du Midi. Photographs were taken with small, high-speed camera and filter combinations which had low detection limits for emission nebulosity.

A further effective method of detecting faint, large-scale nebulosity was also used on this problem. In this, Palomar Sky Survey plates were copied at reduced scale and very high contrast. These were then compiled to form mosaics across the radio features. Faint density changes that were continuous through adjacent plates were considered to be caused by nebulosity.

The results produced by this work are as follows: (a) No filamentary nebulosity was detected on the North Polar Spur. However, a very diffuse optical emission region was shown to be present over this area. As yet it is impossible to say whether or not this is associated with the radio feature. (b) No filamentary nebulosity has been found on the 60° diameter loop. A search for diffuse nebulosity is now being undertaken. (c) It was on the Cetus Arc that the most interesting nebulosity was discovered. This has been sketched against the 237-Mc/s radio contours and presented in Fig. 1. The most striking single feature of this optical emission zone is the huge arc of nebulosity which bounds it. This is of filamentary micro-structure and has so far been traced for a length of 28° . Within this arc, towards the Cetus Arc radio ridge, there is a zone of diffuse elongated filaments. These merge with a structureless optical emission region as the radio

ridge is crossed. This very diffuse nebulosity has not been sketched, as its extent is ill-defined.

The nebulosity are from $\alpha = 4\text{ h } \delta = +13^\circ$ to $\alpha = 3\text{ h } 40\text{ m } \delta = -15^\circ$ is comparable, in position relative to the radio feature and in structure, to the optical emission regions associated with the Cygnus Loop and IC443 (refs. 7 and 8), both of which are accepted supernova remnants. However, a further experiment is required to test conclusively the suggestions that it is associated with the Cetus Arc and that these are the optical and radio remnants of the same supernova explosion; that is, direct comparison of the Cetus Arc with the Cygnus Loop suggests that an angular movement of the Cetus Arc nebulosity can be expected of $1''$ to $3''$ per annum. This motion should be occurring away from the centre of the circle described by the Cetus Arc if this comparison is correct. In this case, during the ten years since the Palomar Plates were taken, where this nebulosity appears, the total angular displacement should amount to $10''$ – $30''$. Such a displacement could be easily detected, for the fine filaments of the nebulosity have similar angular dimensions.

Fig. 1. The nebulosity is shown as a heavily shaded area. The continuous lines are the 237-Mc/s radio contours². Their brightnesses are given in degrees K.

This discovery of filamentary nebulosity bounding the Cetus Arc has strengthened the theory that this object and the other two similar radio features are all supernova remnants. However, the experiment to measure its rate of angular movement could, if positive results emerge, decide this issue conclusively.

PHYSICS

Carathéodory's Principle and the Kelvin Statement of the Second Law

THE second law of thermodynamics has been stated in various ways. The two forms with which this communication is concerned are: (a) Kelvin's principle that it is impossible to transform an amount of heat completely into work in a cyclic process in the absence of other effects. (b) Carathéodory's principle that all points A in thermodynamic phase space are i -points¹; that is, in every neighbourhood of every point A there are points adiabatically inaccessible from A . It has already been shown that (a) implies (b)² and, in this communication, it is proposed to explain in what sense (b) implies (a).

The n -dimensional thermodynamic phase space may be thought of as having $(n-1)$ deformation co-ordinates v_1, v_2, \dots, v_{n-1} and one thermal co-ordinate, which will be taken to be the internal energy, U . By assuming the validity of Carathéodory's principle and the existence of adequate continuity conditions, it may be shown³ that all points in this space which are accessible from some given point P by quasi-static adiabatic processes lie on a single surface, and that P itself must lie on this surface. The argument may be repeated for different initial states P and the thermodynamic phase space is found to be decomposed into a family of non-intersecting surfaces. These are surfaces of constant entropy. Clearly, points lying in different level surfaces cannot be linked by quasi-static adiabatic processes.

In thermodynamic phase space, consider two points A and B ($U_B < U_A$) lying on a line of constant deformation (v_1, v_2, \dots, v_{n-1}). Since each line of constant deformation cuts each level surface in one point, the two points A and B lie in different level surfaces and, hence, cannot be linked by quasi-static adiabatic processes but, either: (i) A is accessible from B by a non-static adiabatic process, or (ii) B is accessible from A by a non-static adiabatic process, but not both. This result is a consequence of Carathéodory's principle and continuity assumptions which represent the basic premises of this communication.

Suppose (i) holds. The system may be taken from B to A by a non-static adiabatic process and the increase in internal energy is due to mechanical work W done on the system. With deformation co-ordinates fixed, the system may be returned from A to B . With the v_i constant, no work is done and the decrease in internal energy is due to heat $Q = U_A - U_B > 0$ having been removed. In this cycle, due to the conservation of energy, an amount of work is seen to be completely converted into heat.

Suppose (ii) holds. With deformation co-ordinates fixed, the system may be taken from B to A . With the v_i constant, no work is done and the increase in internal energy is due to heat $Q = U_A - U_B > 0$ having been supplied. The system may then be returned from A to B by a non-static adiabatic process and the decrease in internal energy is due to mechanical work W done by the system. Due to conservation of energy, it is seen that an amount of heat is completely converted into work in this cycle.

It follows, therefore, that for the cycles considered, either: (1) work cannot be completely converted into heat, or (2) heat cannot be completely converted into work. This multiplicity of possibilities is characteristic of conclusions based on Carathéodory's principle. Unless supplemented by additional assumptions, it leads to four possible types of thermodynamics, all similar in logical structure but distinct in detail¹.

To obtain Kelvin's principle, not only must adequate continuity assumptions be made but it must be assumed that any given cycle can be decomposed into a number of cycles of the type considered here and, in addition, that (2) rather than (1) holds. It is only in this sense that Kelvin's principle may be deduced from Carathéodory's

principle. Of these additional assumptions, the second is seen to be valid in the usual type of thermodynamics (referred to as type I in ref. 1), in which the absolute temperature is positive and heat tends to flow from high to low absolute temperatures. It is the absence of these additional assumptions which gives the converse argument², the deduction of (b) from (a), an attractive simplicity.

The form of Kelvin's principle applicable for negative temperatures states that in a cyclic process, in the absence of other effects, either heat cannot be completely converted into work or work cannot be completely converted into heat⁴. It may be noticed that, apart from the basic premises, only the assumption that any given cycle can be decomposed into cycles of the type considered here is needed to deduce this modified form of Kelvin's principle. It is only if one wants to go further and derive the conventional form (a) of the Kelvin principle that the additional assumption, that (2) rather than (1) holds, must be made.

I thank Prof. P. T. Landsberg for his advice and also for the preprint of a paper by Sears⁵, in which the converse of the argument in ref. 2 is discussed in an alternative way. This work was supported by a scholarship awarded by the Glamorgan County Council.

Ionizing Radiation: a Potential Lightning Hazard?

BENJAMIN FRANKLIN and Michael Faraday were until recently the only major contributors to the problem of preventing lightning damage to man-made structures. The 'Franklin Rod' and the 'Faraday Cage' systems both afford a more conductive path to earth for the lightning strike than that supplied by the structure they are intended to protect.

The electric charges generated in a thunder cloud are not distributed evenly throughout the cloud but form regions of higher intensity of electrostatic charge. It is from these regions to a region of high induced intensity of charge on the earth that the lightning discharge will tend to occur. This is because some points in this region of high intensity on the ground will liberate a stream of positive ions (known as the 'point discharge current'), resulting in a region of ionized and therefore more conductive air extending above this point. The most highly conductive path from cloud to earth is searched out by an initial low-voltage discharge; the so-called 'pilot streamer', which is followed by a second, fairly slow-moving discharge, the 'stepped leader'. This prepares a well-ionized path for the one or more main strikes which follow; these usually involve potentials of between 10^8 and 10^9 V and currents in the range of 20 to 90 thousand amperes.

The probability of any point being selected as the site of a lightning strike depends on many factors, but essentially these can be reduced to two: (1) The height of this point above other prominences in the region; (2) the magnitude of the point discharge current and thus the conductivity of the air above the point. While these factors determine the point in a region which will be struck, other factors, geographical, meteorological, etc.,

make some regions more prone to lightning strikes than others.

In the protection of man-made structures from lightning damage, the most important factor is usually considered to be the height of the building. In Great Britain it is found that churches are struck fifteen times more frequently than private dwelling-houses¹. The estimated frequency of lightning strokes to earth in England is about six per square mile per annum² of which approximately one quarter cause damage to persons or structures.

In recent years a new type of lightning protection device has been developed, and the fact that legislation governing its use has been passed under the 1960 Radioactive Substances Act would suggest that it is becoming widely used. The operation of this device is based on the ability of radioactive material to ionize the air surrounding it, the extent and degree of ionization depending on the activity and nature of the source. Suitably encapsulated radioactive sources are placed slightly higher than the roof of the building to be protected and are carefully earthed in the same way as the traditional devices. Any lightning strike entering the hemisphere of effective ionization caused by the source should be directed along the increasingly well-ionized path, strike the source itself, and be conducted harmlessly to earth. This hemisphere of effective ionization is arranged to cover the entire roof area of the building, and thus the building itself should never be struck as there will always be a more conductive path leading to the well-earthed source.

A commercially available type designed to afford a hemisphere of protection of radius 100 m contains 708- μ c. radium-226. The radiation dose rate at 100 m from a radium source of this size will not be greater than 0.00006 mr./h, and may well be less, due to absorption in the encapsulating material and also self-absorption in the source itself. This extremely small dose rate is considered to produce sufficient ionization to make this path to earth the most likely to be chosen by the lightning, and experiments carried out by the manufacturers are claimed to substantiate the effectiveness of this method. If this is so, the potential hazard due to the lightning-attractive properties of radioactive sources used for medical and industrial purposes would not appear to be widely recognized. This could result in a structure housing a source of ionizing radiation, and therefore presumably a particularly attractive site for a lightning strike, being totally unprotected against this occurrence.

Possibly persons using radioactive material for medical and industrial purposes are not aware of the claims made for the lightning-attractive powers of sources giving small radiation dose rates, or perhaps this aspect of a source used primarily for a totally different purpose has not been considered.

It is of interest to consider the case of a hospital in which kilocurie sources of γ -emitting radioisotope, for example, cobalt-60, are used for radiotherapeutic purposes. Therapy units containing these large sources are commonly installed in single-storey buildings, which are normally not fitted with any earthing system for lightning. The main radiation beam from a rotational therapy unit is frequently directed towards the roof of the therapy room for a percentage of the total treatment time. The attenuation produced by the roof is often minimal (for example, a roof light of ordinary glass) as the radiation scattered from the emergent beam is not considered to constitute a hazard to personnel at ground level.

A typical 3,000-c. cobalt-60 source gives a dose rate of approximately 125 r./min at 65 cm from the source. Allowing for absorption in the patient's body through which the beam passes, a rough calculation reveals that a dose rate of 6×10^{-5} mr./h (that is, the dose rate produced by the lightning protective device at its effective range) will still occur at a height of 62 miles. When the radiation beam is not directed upwards, only scattered radiation emerges through the roof. If one assumes that the intensity of this

scatter is only a ten-thousandth of that of the main beam, this still corresponds to a height of more than half a mile before the dose rate falls below that considered effective to attract the lightning strike to the source.

Many industries use radioactive sources giving local dose rates far in excess of 6×10^{-5} mr./h, and indeed I am aware of such a source used as a density gauge mounted on the upper section of an outdoor chemical plant synthesizing highly inflammable and explosive liquids.

In view of the foregoing, one would expect frequent reports of radiotherapy centres, industrial radiography departments, etc., being damaged by lightning; in fact, the search for reports of such occurrences has revealed only a vague rumour of this having happened once to a radiotherapy centre in the United States.

Must one therefore conclude that: (a) small sources of ionizing radiation are not effective as lightning attractors? or, (b) radiotherapy centres, etc., rarely operate during thunderstorms, and have, so far, been very fortunate?

This is a question to which some answer must be found, as at present neither of the two logical alternatives is satisfactory: either buildings 'protected' by these radioactive devices are in fact not actually protected and may well suffer lightning damage; or, sooner or later, a radiation beam will attract a lightning strike to the source of a tele-isotope unit and, unless this is as effectively earthed as a proper lightning conductor, the effects could be catastrophic. Energies of more than 5×10^{10} watts are usually involved and, apart from structural damage and the possible rupture of the sealed radioactive source, with resultant contamination, one hesitates to contemplate the fate of the unfortunate patient undergoing treatment.

GEOLOGY

Observations on the Mont Pelée Eruption of 1902 and their Significance to Ordovician Welded Tuffs of County Mayo, Eire

DURING recent investigation of some welded tuffs in the Ordovician rocks of eastern Murrisk, County Mayo, lenses of sillar, non-welded material were encountered at the base of the tuff-horizons. Similar layers had previously been reported by Stanton¹ and Dewey² during investigations farther west. Stanton¹ interpreted the variation in thickness of the sillar material as due to differences in the depth of sea-water present before the tuff built up to sea-level, prior to it becoming a truly welded tuff. The entire process was regarded as a 'continuous whole'.

A letter written by the British Consul in St. Pierre on May 3, 1902, some five days before the Peléan eruption which destroyed the town and its inhabitants, has been brought to my attention by Mr. R. A. Japp, of Dundee, together with samples of the early ashes produced during the eruption. With permission, an extract from this letter is relevant:

"I wrote you about the volcano smoking last week. Yesterday afternoon it began to throw out enormous clouds of steam and black smoke from a different place.

"About one this morning I was awakened by a roaring noise, something like thunder and lightning. . . . The houses and street were covered with dust . . . white, as if there had been a snow-storm.

"The dust continued to fall until there was a layer of $\frac{1}{4}$ inch, and is still falling a little. It is all very fine (I enclose sample), and as we have no glass, but only

'jalousie' windows, it drives in and penetrates everywhere . . .

"The volcano is 4 miles from here. A river running from it was swollen with dirty water and mud, and made a great stink . . . Today the smoke and dust have spread—some of the latter having gone beyond Fort de France—20 miles away. I believe there will be no danger . . ."

The sample referred to has now been examined and found to consist principally of a very fine siliceous ash, in which occur broken and angular fragments (up to 0.05 mm in diameter) of crystals of quartz and labradorite feldspar. The labradorite (An_{55-70}) shows both multiple albite twinning and complex oscillatory zoning in which outer zones have sometimes been partly torn from the cores of the crystals. Some magnetite is present, but there are no recognizable shards in this very fine-grained, yellow-green tuff.

This account is of two-fold significance. First, it directs attention to the importance of the preliminary phases of eruption which precede the extrusion and accumulation of Peléan tuffs. Secondly, it indicates that the sillar bases to welded tuffs need not be strictly contemporaneous with the overlying welded material. MacGregor³ and others have pointed out that the terms 'Peléan' and 'welded' tuffs are not necessarily synonymous.

The observation that the nearby rivers were swollen with debris from the early fall-out of ash shows that the loose ashes were rapidly transported to the sea. In areas where shallow water bordered the land, this fine ash would have been rapidly redistributed and deposited on the sea floor. Protracted activity of this type enables appreciable accumulations to develop before the extrusion of the main mass of pyroclastic material. The preliminary phases of such eruptions, therefore, may be responsible for the shallowing of the sea, so that the hot ash falling into the shallow water rapidly builds above water-level, so permitting welding to occur above the non-welded, non-contemporaneous base.

The welded tuffs of western Mayo show non-welded sillar bases in various places. In western Murrisk both Stanton¹ and Dewey² have recorded sillar layers in MT1 and MT2. In eastern Murrisk neither of these tuff layers has a continuous sillar base. Thin lenses are present on MT1, but the base of MT5 has a 4-ft.-thick layer of sillar material in the cliffs to the west of Lough Glenawough. No sillar material is present east of the lake.

The lowermost part of the sillar layer is almost devoid of shards. In places it consists of very fine dust with a few grains of quartz, which show uniform extinction. In the upper part of the sillar layer angular fragments of un-twinned plagioclase An_{25-40} are abundant in the tuff, with less frequent angular quartz grains, a few of which show the deep embayments so common in the quartz grains of the overlying, welded tuffs. Virtually all the feldspar fragments are deeply altered to sericitic material, with the result that they are distinguished with difficulty from the intratelluric material, in which minute undeformed shards are present.

With the change from non-welded to welded tuffs there is an increase in the size of the shards, from 0.01 to 0.04 mm to 0.05 to 0.20 mm. There is an accompanying change in the proportion of included lithic fragments (0.2–3.5 per cent). These two factors may result from changes in the strength of the forces active at different stages of the eruption. Large shards are to be expected from the fully frothing pyroclastic flows, whereas smaller ones result from quieter, less spectacular eruptions of the early phases.

Origin of Fossil 'Zoophycos'

In the Czechoslovak Carpathians I have found imprints, described in the literature from many localities throughout the world as *Zoophycos*, *Taonurus*, *Spirophyton*, etc. The occurrence of these imprints in numerous localities in the Czechoslovak Carpathians is closely related to fine-grained sandstone strata, and sometimes to the marlstones (Cretaceous, Palaeogene). After a detailed investigation I concluded that these imprints were formed by abandoned prostomial parts (gill organs) of sedentary marine worms (Annelida, Polychaeta) from the family Sabellidae¹. The imprints are closely similar to the recent genus *Spirographis* Viviani 1805. As in that genus, the gill rays of the fossil worms are spirally wound around an asymmetrical gill lobe either to the left or to the right side, in the ratio of about 1:1. In sedimentary rocks the gill organs are either perpendicular to the bedding plane or they form flat coinciding accumulations.

The gill organs (prostomium) which are the forepart of the body are easily abandoned by the worms when they are in danger². Abandoned gill organs were formerly considered by palaeontologists as unknown, extinct plants, most probably algae or as a breeding place of marine animals, so that these fossils were regarded for a long time as problematical in origin. They are common in

Africa^{3,4}, America^{5,6}, France⁷, Germany⁸, England⁹, Switzerland⁷, Belgium^{8,9}, Luxembourg⁹, Italy¹⁰, Austria¹¹, Poland¹², Czechoslovakia¹, and the U.S.S.R.¹³, and their occurrence may be recorded anywhere in shallow-water marine sediments all over the world.

Fossil worms lived in a siphuncle as sedentary animals in colonies on the bottom of a shallow sea and, like recent forms, they fed on fine detritus and micro-organisms sinking downwards to the bottom. They received the food by means of their gill organs with variously adapted gill rays. On account of the different shape of the gill rays in fossils from the Flysch of the Czechoslovak Carpathians I proposed several genera. In that area, where these fossils occur in the rocks, a very rapid sedimentation may be supposed.

Due to their systematic classification in the animal kingdom they have become the most common fossils in the stratigraphic as well as in the topographic sense and they ought to have been referred to the zoological system long ago.

METALLURGY

Dispersion-softened Zinc Alloys

A NUMBER of zinc-based alloys containing equiaxed particles of various stable and insoluble hard second phases were prepared as part of an investigation into the high-temperature compression creep characteristics of dispersion-hardened materials¹. It was found that the dispersed particles produced a substantial strengthening effect at temperatures above 0.60 of the absolute melting temperature of zinc. Room-temperature tensile tests were made in order to measure the expected loss in ductility of zinc caused by the hard particles. It was surprising to find, therefore, that most of the dispersed particles reduced the strength and increased the ductility of zinc. These results are briefly reviewed here.

The alloys were prepared by methods of powder metallurgy in order to produce uniform dispersions of ZnO, $\alpha\text{Al}_2\text{O}_3$, carbon black, and tungsten in a void-free zinc matrix. The particle size of these spheroidal dispersoids was typically 0.1–0.6 μ . Two concentrations of second-phase particles were studied: 9 and 15 volume per cent. The composites were obtained in the form of 0.375-in.-diameter extruded rods. Specimens were annealed before testing at 385°C for 24 h. Pure zinc extrusions were also prepared from the same lot of powder as the composites and these were used to establish a basis for comparison.

Typical true stress versus true strain curves are presented in Fig. 1 for a zinc-tungsten alloy and also for a pure-zinc specimen. There are three characteristics to be noted from these curves and from the results in general: (1) The dispersed particles of tungsten actually weaken the metal. It can be seen that both the stress at the onset of plastic flow and the ultimate strength were lower for the composite than for the pure zinc. (2) The particles produced strain softening in zinc. That is, after a period of work-hardening, the effective stress required to deform

further the composite decreased with increasing strain. (3) The composites were considerably more ductile than is pure zinc. These three effects were most pronounced in the zinc-tungsten alloys, but they were also observed in each of the other composites containing spheroidal dispersed particles except for the alloys of zinc containing carbon. The influence of carbon was to embrittle as well as to weaken zinc (for example, 1-5 per cent reduction in area for Zn-C versus 14-23 per cent in pure zinc and 50-93 per cent for Zn-W). Some materials containing zinc oxide in platelet rather than in spheroidal form behaved in a more conventional manner. That is, they were stronger but slightly less ductile than pure zinc.

Fig. 1. Tensile behaviour of a zinc-tungsten dispersion-softened alloy compared to pure zinc. True stress-true strain curves obtained at 26° C and at a strain rate of 2 h⁻¹.

An examination of the slip bands produced in deformed specimens of pure zinc showed that the bands were coarse and widely spaced. Very fine slip lines were observed in the deformed zinc-tungsten alloy and electron microscopy was required to resolve them. Duplex slip, which manifested itself by intersecting slip lines, was common in the composites.

We believe that the fine slip and the duplex slip account for the reduced strength, work softening, and improved ductility that the alloys exhibited. Duplex slip can lead to the intersection of dislocations resulting in the formation of many jogged screw dislocations. Intersection is minimized when slip is restricted to the basal plane. The predominance of duplex slip in the composite alloys suggests that there were many more intersection-induced dislocation jogs in the alloys than in the pure zinc. The motion of jogged screw dislocations will produce an excess vacancy concentration^{2,3} which should aid the climb of dislocations over the dispersed particles. Thus the composite is strain softened and its ductility is enhanced. In addition, the ductility of the composite is high since the presence of fine and duplex slip will give a more uniform distribution of strain than the presence of coarse slip bands as was observed in zinc. It is likely that the fine slip and duplex slip observed are promoted, and indeed may be caused, by the microscopically non-uniform distribution of stresses that must exist in the alloys. This stress field heterogeneity may be caused by stress concentrations near each particle in a specimen subjected to an applied load and it may also be the result of the thermal expansion misfit between particles and matrix that develops when the alloy is cooled from the extrusion or annealing temperature. These internal stresses in the composite can lead to a low yield stress and a low ultimate strength in comparison to pure zinc.

Polycrystalline beryllium and magnesium are similar to zinc in that they exhibit limited ductility at low temperatures. This low ductility is generally attributed to the limited slip systems available in these hexagonal close-packed metals. It is possible that the addition of fine particles of selected high-melting second phases to

beryllium or magnesium may improve their ductility as was observed for zinc.

This work was supported by the Office of Naval Research, U.S. Navy. One of us (W. H. McCarthy) was the recipient of a Gordon Foundation fellowship. The assistance of Mr. D. G. Folger with some of the alloy preparation is much appreciated.

CHEMISTRY

Structure of a Diolefin Complex of Platinum(II) $C_{10}H_{14}O_3PtCl_2$

THE nuclear magnetic resonance and infra-red spectra^{1,2} of potassium *tris* acetylacetonatoplatinum(II) suggest that the acetylacetonate anions form a square planar arrangement around the platinum with one conventional oxygen-bonded acetylacetonate chelate and two γ -carbon bonded ligands. The complex reacts with hydrochloric and hydrobromic acids to give greenish-yellow complexes of composition $C_{10}H_{14}O_3PtX_2$ ($X = Cl, Br$) which are monomeric in chloroform and non-electrolytes in nitromethane. In contrast to the 'acid' derivatives³ of the complex $K[Pt(Acac)_2X]$, these complexes are stable in solution for several days.

The nuclear magnetic resonance spectra of $C_{10}H_{14}O_3PtCl_2$ and $C_{10}H_{14}O_3PtBr_2$ indicate a symmetrical structure with two sets of pairs of methyl protons at 8.3 τ and 7.8 τ and two olefinic protons at 5.5 τ ; the methyl protons have ¹⁹⁵Pt-H coupling constants of 3 c/s (8.3 τ) and 34 c/s (7.8 τ), the protons at 5.5 τ having a coupling constant of 84 c/s. These coupling constants are consistent with the co-ordination of the platinum by olefinic groups with one pair of methyl groups directly bonded to the olefine and one set separated by a number of intermediate atoms. The infra-red spectrum is also consistent with the presence of a co-ordinated olefine grouping ($\nu_C = C = 1,495\text{ cm}^{-1}$) and the absence of a co-ordinated acetylacetonate ligand. A characteristic absorption at 1,236 cm^{-1} implies the presence of an unsaturated ether grouping, the two platinum-chlorine stretching frequencies at 325 and 335 cm^{-1} requiring a *cis*- arrangement of the chlorines in the complex. The identity of the infra-red spectra of the chloride and bromide spectra above 400 cm^{-1} shows that there are no direct carbon-halogen bonds in the complex.

β -Diketones are known to condense with elimination of water to give further unsaturated systems; the presence of only three oxygen atoms in the complex and the absence of an O-H group absorption in the infra-red and nuclear magnetic resonance spectra suggest that such a condensation has taken place in the reaction of $K[Pt(Acac)_3]$ with acids. The structure of the condensation product, which was suggested by the spectral data, has now been confirmed in detail by a single crystal X-ray diffraction analysis. The X-ray data collected, by courtesy of Dr. P. B. Braun, on a 'Paired' automatic diffractometer, have been converged to a present reliability index of 0.060, the overall stereochemistry of the complex being shown in Fig. 1.

The co-ordination of the platinum is approximately square planar with two chlorines, in a *cis* configuration, at a mean distance of 2.31 Å (σ 0.005 Å), and two donor olefinic bonds of mean length 1.45 Å (σ 0.03 Å). The bonding of each olefinic group is asymmetric, the mean Pt-C distances being 2.10 Å and 2.33 Å (σ 0.02 Å). The

Fig. 1

intramolecular platinum-oxygen distances range upwards from 2.89 Å, more than 1 Å greater than is found in the example of the oxygen-chelated acetylacetonate anion in $K Pt(Acac)_2Cl$. The mean lengths of the bridging and remaining C—O bonds are 1.44 and 1.40 Å respectively (each with σ 0.03 Å).

Ultra-purification by Separation of Aerosol Particles

PURIFICATION methods which treat the concentration of a given impurity as a continuous quantity become ineffective when only a discontinuous distribution of that impurity is left in a material. Further purification is feasible on a dispersion principle which makes use of this discontinuity, and by which liquids have been observed free from particles at temperatures too low to cause the latter to be melted or dissolved.

A bulk sample of liquid, which after thorough pre-purification still contains a number of particles, is partitioned into a larger number of droplets which are usually suspended in a particle-free fluid. In the resulting dispersion, the particles are confined to a fraction of the droplets and thus isolated from the rest of them^{1,2}.

Liquid dispersions of metals¹⁻⁴, water⁵⁻⁷, organic compounds^{8,9}, and alkali halides¹⁰, of uniform droplet size, were subjected to under-cooling. Meanwhile, the droplets were observed either collectively or singly; their solidification was detected by inoculation of under-cooled bulk liquid⁵, by optical effects, for example, recalescence flashes³, twinkling^{8,10}, or X-ray diffraction⁴, and by other techniques. A portion of the droplets did not freeze until, far below the melting point, the critical under-cooling temperature had been reached. There is evidence that these droplets crystallized by homogeneous nucleation and therefore were free from heterogeneous impurities. Homogeneous impurities did not alter very much the critical under-cooling temperature⁹, unless, as in emulsions, they were occluded in the particles⁹.

The isolation of particle-free liquids was always incidental to the investigation of other topics and the possibility of using it to produce these liquids in appreciable quantity does not seem to have been realized. For example, a drop (2 mm diameter) of particle-free water, stored at the interface between two immiscible liquids, was instead obtained by multiple distillation without ebullition⁷.

Large samples of liquids free from particles could be produced from aerosols by separating contaminated from uncontaminated droplets. When the temperature of a monodisperse liquid aerosol is held slightly above the critical under-cooling point, all droplets containing particles are frozen. By ultra-sound of a wave-length comparable with the diameter of these droplets, the particle-free liquid droplets can then be sub-divided further. The resulting difference in particle size causes the contaminated particles to sediment before the uncontaminated ones.

Bulk samples of materials could similarly be purified from the last traces of a given homogeneous impurity. The properties of the latter determine the technique by which the aerosol particles are separated. In the case of impurities amenable to uninterrupted selective heating, it is advisable to utilize the very large negative temperature coefficient of the rate of crystallization of particle-free droplets. The noble gas, in which the monodisperse liquid aerosol is suspended, is cooled to the critical under-cooling temperature. Then only the contaminated droplets, which are subjected to induction or to high-frequency dielectric heating, remain liquid and can be dispersed ultrasonically. In other cases, for example, contaminated aerosol particles could be photo-ionized selectively by ultra-violet radiation, and electrostatically precipitated.

According to the dispersion principle, the fraction of particles free from impurities increases with the degree of dispersion. Volatile covalent compounds can be dispersed to discrete molecules within an involatile inert matrix. This makes it possible to purify small quantities of such compounds by fractional molecular distillation, in which these molecules are separately evaporated by selective infra-red radiation¹¹. The high cost of this method limits it to laboratory use.

As a guest in this Institute, I thank Prof. W. Jost for his hospitality.

Polyamide Layer Chromatography of Oestrogens

THE oestrogens were investigated by Struck¹ and Lisboa *et al.*² by thin-layer chromatography using silica-gel. The solvent systems for the silica-gel thin-layer were well-established ones which have been used for quantitative purposes³. On the other hand, Woltz and Chatteraj⁴ combined thin-layer and gas-chromatography to identify the minor oestrogenic substances in female urine.

Since oestrogens contain a phenolic group in their molecule, it is conceivable that polyamide can be used

	Table 1	
	Chloroform-butanol (95:5)	Ethanol-water (60:40)
Oestrone	0.82	0.35
Oestradiol (17- β)	0.55	0.32
Oestriol	0.21	0.48

for their separation⁵. The polyamide layer, according to Wang⁶, was applied to oestrone, oestradiol and oestriol, and both chloroform-*n*-butanol (95:5) and ethanol-water (60:40) systems showed excellent resolution (Table 1 and Fig. 1). This suggests that quantitative separation of oestrogens of complex biological fluid can be done by column chromatography with polyamide powder. It is also possible to investigate minor oestrogenic substances by means of two-dimensional polyamide layer chromatography.

Fig. 1. Polyamide layer according to Wang (ref. 6). *a*, Solvent: chloroform-*n*-butanol (95:5); time: 1.5 h (10 cm). *b*, Solvent: ethanol-water (60:40); time: 2.5 h (11 cm). Samples, 1, oestrone; 2, oestradiol (17- β); 3, oestriol. Detection: diazotized sulphanilic acid

It was stated by Carelli *et al.*⁵ that hydrogen bonding of the phenolic group is the main force of polyamide sorption of phenols, and he has suggested a neighbour group 'screening effect'. If this is true, the oestrogens may show only a small difference on a chromatogram because they have a similar substitution pattern on the phenol ring. Differences occur, however, in the alcoholic hydroxyl groups, which are at distant sites on the 16- and 17-carbon atoms. Contrary to prediction, the chloroform-butanol system shows a marked difference in *R_F* values. It is best to assume that the alcoholic hydroxyl group in the oestrogens has some effect on their sorption to polyamide since an increase in hydroxyl groups also leads to an increase in the adhesion of substances to polyamide.

On the other hand, the fast-moving spot using an ethanol: water system is oestriol, and oestradiol is slower — oestrone is very close to oestradiol.

Although the presence of water affected the affinity of oestrogens for polyamide, it seems too early to suggest a polyamide sorption mechanism by the ethanol-water system as for the paper chromatographic-type partition process put forward by Copius-Peereboom⁷: in true partition by paper chromatography⁸, oestrone is the faster and oestriol remains at the origin, while oestradiol is intermediate between the two. There is the same tendency with chloroform-*n*-butanol systems of polyamide-layer chromatography. Our experiments on oestrogens suggest that further elaboration of the sorption mechanism is necessary.

Slow Inversion at the Nitrogen Atom in Certain Amides

It has long been considered that nuclear magnetic resonance (NMR) should be a suitable technique for the demonstration of slow inversion in trivalent nitrogen compounds. However, only in the case of cyclic imines, such as *N*-ethylethylenimine, has it been possible to demonstrate slow inversion by NMR¹. Recently, Saunders and Yamata² searched for evidence of slow inversion in dibenzyl methylamine, but found no evidence for non-equivalence of methylene protons in the amine itself. They were successful, however, in observing non-equivalence in the amine hydrochloride.

We wish to report evidence for slow inversion in the proton magnetic resonance spectrogram of *N*-benzyl-*N*-(orthomethyl) phenyl acetamide (I) and related compounds. The spectrogram of this compound is compared with those of *N*-benzyl acetanilide (II) and *N*-benzyl-*N*-(2,6-dimethyl) phenyl acetamide (III) in Fig. 1. The pertinent feature in the spectrogram of (I) is the multiplicity (four peaks) of the signal for the methylene protons. We have analysed these signals as an *AB* pattern with a chemical shift of 0.83 p.p.m. and a coupling constant of 14 c/s. The intensity ratio of the inner to outer lines is predicted to be 1.74 for such a pattern and was observed to be 1.67.

If a mechanism for a rapid exchange of identities of the methylene protons existed, the *AB* pattern would not be observable. Rapid inversion at the nitrogen atom is such a mechanism. From this it follows that inversion must be less rapid than a mean lifetime of something like 1–10 milliseconds.

The lack of observable non-equivalence in II and III indicates that a fairly high order of dissymmetry in the molecule is required. The requirement of a high degree of dissymmetry may be the reason that slow inversion has not been observed for acyclic trivalent nitrogen in the past. Evidently even the

Fig. 1. Proton magnetic resonance spectrograms of three acetanilides at 60 mc/s

presence of three different substituents is not a guarantee of observable non-equivalence.

We have observed this type of non-equivalence in a number of related compounds and are continuing our study of this phenomenon.

These investigations were carried out in the course of work under contract AT(07-2)-1 with the U.S. Atomic Energy Commission.

BIOCHEMISTRY

Proteins of Wheat Flour

A NUMBER of reports have recently been published concerning investigations of the 'zwickel' (wedge) and 'haft' (adhering) protein fractions of wheat flour and their influence on the separation of flour fractions of different protein content by air-classification procedures^{1-4,11}.

These fractions were originally described by Hess, who believed that flour or endosperm proteins in the native state existed in two forms, one as a network of fibrils on the surface of the starch granules and covered by a layer of lipid ('adhering' protein), and the other as discrete particles between the starch granules ('wedge' protein). These two fractions were readily separated by differential

centrifugation in non-aqueous media and differed significantly from the equivalent fractions of the gluten isolate⁸. Hess concluded that during the conversion of native protein to gluten, mechanical treatments cause a structural chemical alteration of the protein molecules.

Jones *et al.*⁹ have shown that flour fractions separated on the basis of particle size contain different amounts of protein. Up to about 17 μ the particles include fragments of free protein with a relatively high protein-to-starch ratio. Particles of 17-35 μ contain a large proportion of free starch granules and are consequently low in protein content. Above 35 μ the particles consist of larger detached starch granules and pieces of unbroken endosperm cells and may have a similar or higher protein content than that of the parent flour¹⁰. These differences have provided the bases for the industrial air-classification of flours in the sub-sieve range (<40 μ).

Results obtained by Stevens *et al.*², based on amino-acid analyses, indicate that proteins of the 'gliadin/glutenin' type are preferentially extracted in flour fractions of small particle size (<17 μ), while the more soluble fractions appear to be associated with those fractions of larger particle size containing more starch. Protein analyses of Elton and Ewart, however, failed to indicate significant differences between these fractions⁴.

A number of workers have recently examined the protein composition of air-classified fractions using some of the newer, refined techniques of protein fractionation in an attempt to confirm Hess's original classification^{1,3,4,11}. In most cases the protein composition of these fractions differed little from that of the parent flour.

In this laboratory, the protein compositions of a number of air-classified flour fractions were examined by starch-gel electrophoresis following the methods described in previous reports^{3,12}. Acetic acid extracts (2.0 g/6 ml., 0.01 N) were indeed found to vary little from those of the parent flour.

Samples of 'wedge' and 'adhering' protein obtained from the late Prof. Hess's laboratory when similarly examined however, showed significant differences in protein composition. 'Wedge' proteins corresponded mainly to endosperm components of low electrophoretic mobility (gliadins), while 'adhering' proteins corresponded to the slowest-moving endosperm fractions together with smaller levels of components of intermediate electrophoretic mobility (albumins). Densitometric scans of these starch-gel patterns are shown in Fig. 1.

Fig. 1. Starch-gel electrophoresis of 'wedge' (solid line) and 'adhering' (broken line) proteins of wheat endosperm. Buffer: aluminium lactate-lactic acid. Voltage gradient: 8-10 V/cm⁻¹. Time, 3 h

The obvious association of 'wedge' proteins with the generally accepted gliadin fractions and those fractions adhering to the starch granules with the albumins would seem to conform with recent findings. The fact that the 'adhering' protein appears to represent mainly a distinct group of components of lowest electrophoretic mobility would seem to confirm the original observations of Hess. Protein fractionation by air-classification would therefore seem to be much less complete when carried out on the present commercial scale.

A further interesting fact, which may be of some significance in this context, emerged from a comparison of the solubility characteristics of flour and isolated gluten proteins. Aqueous extracts of flour and gluten, isolated from an equivalent amount of the same flour, were shown to contain a rather different proportion of protein components (Fig. 2). The latter contained a greater proportion of the slow-moving fractions with the exception of those of lowest electrophoretic mobility. Again the fractions of

Fig. 2. Starch-gel electrophoresis of the water-soluble proteins extracted from flour (broken line) and the equivalent amount of isolated gluten (solid line)

lowest mobility were associated with the albumin components. This could not be explained merely in terms of starch-dilution effects. Similar examination of aqueous extracts of doughs aged for various periods gave protein patterns identical with those of flour. It would therefore seem that the removal of starch during gluten isolation involves not only the removal of the bulk of the water-soluble albumins but also the fractions of lowest electrophoretic mobility, that is, those fractions associated with the starch granules.

We thank Dr. Niederaur, Institut für Mehl und Eiweissforschung, Hanover, for samples of 'wedge' and 'adhering' protein; Messrs. J. and R. Snodgrass, Ltd., Washington Mills, Glasgow, and Messrs. Spillers, Ltd., Old Change House, Cannon Street, London, for air-classified flours, and the Hercules Powder Company, Inc., for financial support.

Tumour-promoting Agents in Unburned Cigarette Tobacco

UNBURNED American cigarette tobacco is an excellent source of tumour-promoting agents¹. The aqueous extract from as little as one-half cigarette per day is sufficient to produce skin tumours in mice painted previously with 125 µg of 7,12-dimethylbenz[*a*]anthracene (DMBA). The work recorded here gives further information about the properties of the active substance.

For most of the experiments, the paper was removed from commercial cigarettes and the tobacco was extracted with aqueous barium hydroxide which was afterwards neutralized with carbon dioxide and filtered. This method provides an extract containing 0.6–0.7 g of solids per ml.¹. In one experiment, however, unprocessed commercial flue-cured tobacco was used in order to determine whether the tumour-promoting activity was due to the unburned tobacco itself, or to the several additives used in the preparation of American cigarettes. Flue-cured tobacco was less active than prepared cigarette tobacco as a source of promoting agents.

ICR Swiss female mice, 55–60 days old, were painted once with 125 µg of DMBA dissolved in 0.25 ml. of acetone. After a period of three weeks, the animals were painted five times weekly with 0.25 ml. of the various test solutions. The animals were examined weekly and the number and distribution of tumours noted. The experiments were terminated after 26 weeks of this second, tumour-promot-

ing stimulus. The biological assay system has been described more fully in other publications^{1,2}.

Each test fraction was assayed at two concentrations, the second one-half the concentration of the first. In this way a semi-quantitative comparison of various fractions was possible.

An attempt was made to fractionate the aqueous extract into acidic, neutral, and basic materials by liquid-liquid extraction techniques. However, stable emulsions of organic and aqueous phases resulted, and it was decided instead to use ion exchange resins. The neutralized aqueous extract (133 c.c. from 267 g of tobacco) was made acidic (pH 1.5) with hydrochloric acid and the solution was then passed through a column (45 × 420 mm) containing a strong-acid cation exchange resin ('Rexyn AG 50(H)'). The column was afterwards washed with distilled water until the washings were colourless. The effluents from this column were then passed sequentially through a similar column containing a strong-base anion exchange resin ('Rexyn RG1 (OH)'). The second column was also washed with water. The effluents from the second column were condensed to provide the neutral fraction. The 'AG 50' column was treated with 4 per cent barium hydroxide until Ba⁺⁺ came through the column and the effluent was colourless. The combined effluent was neutralized with carbon dioxide, filtered and condensed to provide the bases plus amphoteric compounds. The 'RG1-OH' column was washed with 1 N sulphuric acid until the effluent was colourless and the SO₄⁼ came through the column; the combined effluent was neutralized with barium hydroxide, filtered, condensed and labelled 'A' (acids). Half of each fraction was pooled to provide a reconstituted starting material that was identical to the starting material except for changes due to the experimental manipulations. The bioassays showed that much of the activity was lost (Table 1). It did not appear in any fraction or in the reconstituted crude material. The active material probably was either decomposed or not eluted from one of the columns.

A second experiment was conducted to determine whether the active material in the aqueous barium hydroxide extract would dissolve in acetone so that it might be more easily fractionated. Acetone was considered as a possible solvent because acetone-benzene extracts of cigarette tobacco have been found to be active tumour promoters¹. When the aqueous extract was condensed to remove the water, acetone did not mix with the gummy product and incomplete extraction was apparent. There-

Table 1. ACTIVITY OF 'ACIDIC', BASIC, AND NEUTRAL FRACTIONS

fore, the dilute aqueous extract was treated with two volumes of acetone with continuous stirring, whereon a precipitate settled out. The solution was decanted and condensed to low volume and additional acetone was added, precipitating more material. This process was repeated three more times; each time additional precipitate formed. The final solution was condensed and redissolved in a 1:1 acetone-water mixture. The precipitates were pooled and dissolved in water. As before, a reconstituted starting material was prepared by using appropriate amounts of the acetone soluble and acetone insoluble fractions. The results of the bioassays (Table 2) indicated that at least a part of the active material appeared in the acetone soluble fraction. There was no demonstrable activity in the acetone insoluble fraction. A possible loss of activity during experimental manipulation was indicated by the decreased number of tumours produced by the reconstituted crude material and by the acetone soluble fraction.

To measure the stability of the tumour promoters, additional aqueous barium hydroxide extract was adjusted to pH 3, 7 or 11 using sulphuric acid or barium hydroxide. The solutions were then allowed to stand in subdued light at room temperature. After 5 days, they were neutralized with sulphuric acid or barium hydroxide, filtered and tested on mice. The bioassays showed no evidence that the tumour promoters were unstable (Table 3). In fact, there was an increase in activity during standing, especially at the highest pH level. This increase, however, was only moderate as indicated by low activity of the diluted samples.

The volatility of the active material was tested by distilling the neutralized aqueous extract at a pressure of 18 mm to a final temperature of 27° C. One-half of the distillate and one-half of the viscous residue were pooled to produce a reconstituted starting material. The remaining distillate and residue was diluted with water to the original volume from which it was derived. Under the conditions of the distillation, the tumour promoters were non-volatile (Table 4). The residues appeared to be more active than the starting crude product, but again, this increased activity was lost by 1:1 dilution. The distillate was inactive.

The results of these various experiments suggest to us the following tentative conclusions: (1) The tumour promoter of the alkaline aqueous extract and the acetone-benzene extract of cigarette tobacco are closely related, if not identical. (2) The active material is either very highly bound to one of the ion exchange resins, or it is insoluble at extreme pH so that it is not eluted by the concentrated reagents that we used. (3) The active

material may be produced through the degradation of precursor materials in the extracts or in the leaf itself. There was a slight increase of activity when extracts were allowed to stand—particularly at elevated pH.

The biological assays of the active material indicated a definite threshold level. This is clear in every experiment. A 1:1 dilution caused almost complete loss of activity in every fraction. Thresholds are characteristic of tumour promotion and have been investigated extensively by Boutwell².

It was pointed out to us⁴ that the behaviour of the active material is similar to the behaviour of tobacco pigments which have been found in several types of tobacco⁵⁻⁸. The pigments are soluble in alkaline aqueous solution but are precipitated at very low pH. They are, in part, soluble in alcohol. They are complex compounds containing the polyphenols rutin and/or chlorogenic acid bound to proteins or polypeptides. Conceivably, these pigment materials might be degraded on standing to liberate smaller polyphenolic compounds. Furthermore, relatively low molecular weight polyphenolic compounds have been found in flue-cured tobacco⁶. It is of interest that, other than croton oil constituents, the most active known tumour-promoting agent is the polyphenol, anthralin (1,8,9-anthratril)². We are at present testing tobacco pigments isolated by a method developed by Chortyk and Stedman⁴ to determine whether these compounds or their hydrolytic products can account for the tumour-promoting activity exhibited by extracts of cigarette tobaccos.

Synthesis of Ribonucleic Acid by *Escherichia coli* during Inhibition by Azetidine-2-carboxylic Acid

In bacteria, amino-acids are needed in small amounts for the synthesis of ribonucleic acid (RNA) to occur¹ and, if an amino-acid auxotroph is starved of its required amino-acid, both protein and RNA synthesis cease². However, under certain conditions this 'stringency' is not maintained, in that protein synthesis can be sharply retarded while synthesis of RNA is less affected. In *Escherichia coli*, this differential synthesis of RNA can be brought about by incubation of cells with chloramphenicol³, puromycin⁴, or chlorotetracycline⁵, and mutants in which the control of RNA synthesis by amino-acids is 'relaxed' have also been described^{6,7}. Relaxed mutants which require an amino-acid for growth continue to make RNA when starved of their amino-acid requirement; synthesis of RNA in a relaxed strain during inhibition of protein synthesis by 5-methyl tryptophan has also been demonstrated⁸.

Differential synthesis of RNA has now been found to occur when cells of the stringent strain *Escherichia coli* K12 are inhibited by azetidine-2-carboxylic acid. This compound, while inhibiting growth, appears also to be incorporated into protein in place of proline⁹: in plants and rat liver the formation of an azetidine-2-carboxylic acid-transfer-RNA complex is apparently mediated by the

proline-activating enzyme¹⁰. Table 1 shows the results of adding azetidine-2-carboxylic acid (100 µg/ml.) to *Escherichia coli* K12 growing exponentially with a mean generation time of 70 min in a mineral-salts medium. There was an immediate slowing of protein synthesis, which, after 30 min, had been inhibited by 59 per cent; in this same period no inhibition of synthesis of RNA occurred. RNA was afterwards made at a reduced rate, but after incubation for 2 h in the presence of the analogue, the ratio of newly synthesized RNA to newly synthesized protein in the inhibited cultures was nearly twice that in the controls. Similar experiments were also carried out with the relaxed methionine-requiring mutant 58-161 of *Escherichia coli*. As shown in Table 1, addition of 100 µg/ml. of azetidine-2-carboxylic acid to cultures growing exponentially (mean generation time 75 min) produced an immediate strong inhibition of protein synthesis very similar to that observed in the stringent strain. However, RNA synthesis was initially stimulated appreciably and, although considerable inhibition developed at later times, this was less than in the stringent strain. Over a 2 h period, cells treated with the analogue synthesized about 2.5 times as much RNA per unit of newly made protein as did untreated cultures.

Table 1. SYNTHESIS OF RNA AND PROTEIN DURING INHIBITION BY AZETIDINE-2-CARBOXYLIC ACID

Organism	Time (min)	RNA (c.p.m./ml.)		Protein (c.p.m./ml.)		Inhibition (per cent)	
		Control	Inhibited	Control	Inhibited	RNA	Protein
<i>E. coli</i> K12	30	140	140	60	25	0	59
	60	430	280	145	40	35	72
	120	1,175	455	360	75	61	79
<i>E. coli</i> 58-161	30	410	515	180	95	-26	47
	60	1,075	1,055	425	165	2	61
	120	2,465	1,815	975	305	26	69

Cells were grown overnight with aeration and at 30° C in a mineral-salts medium containing DL-methionine (50 µg/ml.) and a limiting amount (66 µg/ml.) of glucose. Excess glucose (7 mg/ml.) was added to re-start growth and, after 60 min, aliquots were transferred to flasks containing uracil and cytosine (final concentration 20 and 15 µg/ml., respectively) and aeration continued. RNA and protein synthesis were followed separately by the addition of [2-¹⁴C]uracil (20 mµc./ml.) and [3-³⁵S]methionine (30 mµc./ml.) in the absence and presence of L-azetidine-2-carboxylic acid (100 µg/ml.). Measurements were made after the addition of the analogue and were of the radioactivity of cells precipitated with 5 per cent trichloroacetic acid at 0° C. Radioactivities were measured at infinite thinness with a gas-flow counter.

It has been suggested that the control of RNA synthesis by amino-acids may be mediated not by the amino-acids as such, but by their complexes with transfer-RNA. Species of transfer-RNA uncombined with amino-acids may cause repression of RNA synthesis; when molecules of transfer-RNA are joined to their specific amino-acids the repression is lifted and synthesis of RNA can continue^{7,11}. On this hypothesis differential synthesis of RNA in the presence of azetidine-2-carboxylic acid may occur in the stringent strain K12 because the analogue can undergo activation and be incorporated slowly into protein. Although protein synthesis is inhibited, uncombined transfer-RNA molecules may not accumulate immediately and synthesis of RNA is not retarded. In the relaxed mutant 58-161, differential synthesis of RNA may be made greater by the genetic defect in the control of RNA which exists in this strain.

'Lipid A' Component from the Cell-walls of *Pseudomonas aeruginosa*

CONSIDERABLE attention¹ has been paid to the lipopolysaccharide complexes which are found in the cell walls of Gram-negative bacteria. The extraction of whole cells or of isolated cell walls with aqueous phenol provides these lipopolysaccharides. The lipopolysaccharide component may be hydrolysed by dilute acid to give 'lipid A' and sugar. Nowotny² has suggested the following structure for the 'lipid A' derived from some strains of *Salmonella*.

F, fatty acid; GA, D-glucosamine; P, phosphoric acid.

Burton and Carter³ have recently isolated the 'lipid A' fraction from whole cells of *Escherichia coli* and, while agreeing in the main with the structure postulated by Nowotny, they point out that their findings would suggest that the D-glucosamine units are linked glycosidically and not by means of phospho-diester linkages. The precise arrangement and the identity of some of the fatty acid constituents of 'lipid A' remain undetermined.

The results obtained in our laboratories during an investigation into the structure of the cell walls of *Pseudomonas aeruginosa* agree with those of Burton and Carter and would support the suggestion⁴ that this type of structure is widely distributed in Gram-negative bacteria.

The cell walls of *Pseudomonas aeruginosa* were isolated by the method of Salton⁵, and phenol extractions of the isolated cell walls were performed as described by Westphal⁶, with the modification that the residue from the first extraction was again treated with phenol. The two phenol layers were combined and fraction PhMP was obtained by precipitation with methanol, while fraction PhMS remained in solution. The two aqueous layers were treated separately, giving rise to Aq I and Aq II as shown below.

Aq I	Aq II	Residue (R)	PhMP	PhMS
20-30%	11-13%	12-15%	20-28%	17-20%

Fraction PhMS contains 80 per cent lipid (cephalin and free fatty acids) and 20 per cent protein, while fraction PhMP is practically pure protein. The residue R is derived from the emulsion between the aqueous and phenolic layers and is a mixture consisting mainly of mucopeptide and protein. Detailed analyses of these fractions will be reported at some other time.

Although Aq I and Aq II showed some variation in quantity and elemental composition from extraction to extraction, all our information so far leads us to believe that they contain two lipopolysaccharide-mucopeptide complexes, and that Aq I and Aq II differ only in the relative proportions of these two major components.

The lipid fraction was obtained by mild hydrolysis of Aq I with boiling 1 N aqueous sulphuric acid for 30 min followed by extraction from the hydrolysate with chloroform, while the remaining aqueous layer contained D-glucose, L-rhamnose, D-glucosamine, and D-galactosamine. After removal of the acid from this aqueous layer and freeze drying, the infra-red spectrum of the residue revealed no indication of lipid material. Fractionation of the lipid on silicic acid gave two main fractions. The first fraction, presumably formed by partial degradation of 'lipid A', contained ester-bound fatty acid and free fatty acid. Thin-layer chromatography showed that the range of fatty acids was practically identical with that obtained by vigorous hydrolysis of Aq I with 6 N aqueous acid. This range included a number of acids, both saturated and unsaturated, up to about C₁₈, and also two unknown acids with high R_F values.

The second fraction was the whole 'lipid A', and the infra-red spectrum was almost identical with that obtained

Fig. 1. The infra-red spectrum of 'lipid A' from *Pseudomonas aeruginosa*

by Burton and Carter for the 'lipid A' obtained by hydrolysis of the lipopolysaccharide from *Escherichia coli*. Examination of the infra-red spectrum of our 'lipid A' (Fig. 1), particularly in the region 750–1,000 cm^{-1} , shows the presence of moderate absorptions which Barker *et al.*⁷ associate with glycosidic linkages. Our findings thus agree closely with those of Burton and Carter and would support their suggestion that the D-glucosamine units are linked glycosidically.

Isozymes of Arylamidase (Aminopeptidase): Source of Blood Aminoacyl Naphthylamidase in the Rat

THE qualitative approach provided by histochemical techniques makes it possible to localize enzyme activity in tissues. This, combined with the use of quantitative and other analytical methods such as electrophoresis, may help in tracing the origin and fate of an enzyme in the blood serum. This rationale has been applied in this study to certain proteolytic enzymes to which the names of aminopeptidase, arylamidase and aminoacyl naphthylamidase have been applied¹⁻³. In this report the three names are regarded as being synonymous.

In the rat, blood levels of aminopeptidase vary within a narrow range in normal conditions⁴. There is electrophoretic evidence that renal aminopeptidase, localized in cells of the proximal tubules, is the source of the urinary isozymes which are distinct from the serum aminopeptidase isozyme⁵. Certain other cells of the rat, such as columnar cells of the small intestine, hepatic parenchymal cells, prostatic epithelium, parathyroid cells, fibroblasts, macrophages, mast cells and heterophiles, contain histochemically demonstrable aminopeptidase. In order to establish a correlation between serum and tissue arylami-

dases in the rat, blood serum and supernatants of homogenates of liver, prostate, small intestine mucosa, and skin were subjected to electrophoresis in a starch-gel medium.

Prostate was homogenized at a concentration of 400 mg/ml. and liver at a concentration of 600 mg/ml. A segment of jejunum was resected. The mucosa was rinsed out gently with saline and the intestine was then cut open lengthwise. The mucosa was scraped off with a razor blade. Fragments of mucosa were homogenized at a concentration of 400 mg/ml. Tissues were disintegrated for 10 min in a Potter-Elvehjem homogenizer. Homogenates were spun at 4,000 r.p.m. in a cold centrifuge at 4° C for 45 min. Supernatants were used as enzyme sources.

An area of skin was thoroughly shaved, and the epidermis scraped off. This area, resected without including muscle or subcutaneous tissue, was minced with a razor blade. 600 mg of skin were weighed out and transferred into a homogenizing tube to which 1 ml. of distilled water was added. The sample was homogenized for 10 min while the tube was kept in dry ice. 0.5 ml. of distilled water was added and, after homogenizing for 1–2 min, the supernatant was poured into another tube and the unhomogenized plug was discarded. The supernatant was spun in a cold centrifuge at 4° C for 45 min at 4,000 r.p.m. The clear supernatant was used.

Serum and supernatant of homogenates of these organs were subjected to zone electrophoresis in a starch-gel medium⁶. A 'Heathkit' regulated power supply was used. 6.5 V/cm was kept during the time of electrophoresis, which was 6 h, at room temperature. At the end of this period, gels were sliced and incubated for the demonstration of aminopeptidase as described in a previous publication⁶. 10 experiments were performed for each enzyme source. A diagram representing the average rate of migration of proteins with aminopeptidase activity is reproduced in Fig. 1.

Fig. 1. Starch-gel electrophoresis of rat blood serum and tissues

Two isozymes were present in each of the organs that were studied; an isozyme remaining at the origin, and a migrating isozyme. The moving isozyme showed different but fairly similar rates of migration for each organ. The serum isozyme is most closely duplicated by the skin isozyme, suggesting that this organ might be the source of blood arylamidase.

Dermal fibroblasts showed characteristic reactivity for arylamidase⁴ (Fig 2). These cells extended all through the dermis. They were of laminar appearance with pro-

Fig. 2. Rat dermis. Aminopeptidase (L-alanyl-4-methoxy-2 naphthylamide HCl). Fibroblasts with processes intensely stained. There is an active vascular crevice in the upper left corner of this cell. ($\times 1,250$)

cesses extending along collagen bundles and abutting on small vessels in which endothelial cells were also active for aminopeptidase. This suggests that aminopeptidase of fibroblasts may be the main or only source of serum aminopeptidase.

It has been suggested on the bases of the study of similar enzymes in man that liver aminopeptidase might be the source of the serum enzyme⁷. It would seem probable that liver aminopeptidase, which by histochemical technique is localized in the peribiliary zone in dense bodies and in bile canaliculi, would be represented by the isozyme remaining at the origin. The moving hepatic isozyme resembled closely serum isozyme. Different results have been obtained for bile of man: one peak coinciding with the serum isozyme⁸ or 2 peaks with incomplete resolution, one at origin and the other migrating like the serum isozyme⁹. Bile duct obstruction in man leads to a new aminopeptidase band at origin in serum^{8,9}. This would suggest that the latter is a membrane-bound form which is also found in bile and would correspond to the bile canaliculi and dense body arylamidases.

It is concluded that, in the rat, the serum isozyme of aminopeptidase originates in the mobile isozyme of skin. Since fibroblasts are the main source of skin aminopeptidase, it is suggested that the soluble fraction of fibroblasts aminopeptidase is the main, if not the only, source of the serum isozyme, and that electrophoretically mobile liver isozyme represents cleared enzyme from serum appearing in bile. Experiments are being made to test this hypothesis.

I thank Mrs. Hannah Wasserkug for technical assistance. This investigation was supported by U.S. Public Health Service grant AMO 3219.

Evidence for the Release of Individual Amino-acids from the Resting Human Forearm

THE study of differences in concentration of substances in arterial and venous blood is well-documented, and offers a method for investigating peripheral metabolism.

In order to study this aspect of amino-acid metabolism in man, cannulation of the brachial artery and brachial vein of the same limb¹ was carried out in six subjects, four of whom were normal, one convalescing from a myocardial infarction and one suffering from benign essential hypertension. All the experiments were carried out at 10 a.m., after an overnight fast. Two simultaneous arterial and venous blood samples were withdrawn from each individual; there was an interval of 30 min between the pairs of specimens. Immediately before and again after a blood sample had been taken, the forearm blood-flow was measured by plethysmography with a mercury-in-rubber strain-gauge² and was shown to be constant. During the blood-flow measurements and while the samples were being taken, an occluding cuff around the wrist was inflated to a pressure that was 100 mm mercury above the systolic blood pressure. Soon after the blood had been withdrawn, it was centrifuged in the cold, the plasma protein precipitated with 1 per cent picric acid³ and stored at -15°C until analysed by automatic ion-exchange chromatography⁴. The means of the two arterial and the means of the two venous amino-acid measurements from each person were used for calculating the mean differences found in the group.

Table 1 shows the mean difference in venous and arterial amino-acid concentrations, expressed as a percentage of the arterial concentration, and also the differences themselves, in $\mu\text{moles}/100\text{ ml. plasma}$, in the group of six subjects. The significance of the differences, calculated by testing against the null hypothesis using both tails of the 't' distribution⁵, is also shown. During the time taken for the experiment there was no evidence of a downward drift in either arterial or venous concentrations. The venous levels were, apart from alanine, within the range delineated in a large range of normal men and women⁶. In the present series of experiments the range of alanine concentrations was 21.2–29.3 and the mean was 26.3 $\mu\text{moles}/100\text{ ml.}$

Table 1. DIFFERENCES IN CONCENTRATIONS OF PLASMA AMINO-ACIDS (VENOUS-ARTERIAL) IN THE RESTING HUMAN FOREARM

Amino-acid	Diff. (per cent)	P	Diff. ($\mu\text{moles}/100\text{ ml.}$)	P

Arginine	16	0.025	1.28	0.02

* Estimated as serine.

The results indicate that, under the experimental conditions used, there is for some amino-acids, including many that are considered to be essential, a significantly higher concentration in venous than in arterial blood plasma; thus at rest and while fasting there is a release of individual amino-acids from the human forearm.

Furthermore, since there is a difference between arterial and venous plasma in these experiments, it may be important to measure arterial concentrations in investigations of movements of amino-acids between intra- and extra-vascular sites.

We thank Prof. F. T. G. Prunty, Drs. R. D. Lowe and I. M. Young and Mr. A. St. G. Davies for their help, and the Wellcome Trust for a grant enabling us to obtain the automatic amino-acid analyser.

PHYSIOLOGY

Quantum Energy Specificity of Simple Photoreceptor Units

THE compound lateral eye of *Limulus polyphemus* has been useful in basic visual function research^{1,2}. *Limulus* ommatidia share similarities in photopigment³, scotopic luminosity function⁴, lateral neural inhibition⁵, and other functions with the scotopic mammalian retina. Light excitability of *Limulus* functional visual receptor units may be modified reversibly by doses of X-rays smaller than required for visual cell pathology⁶. X-ray excitation of *Limulus* ommatidia⁶ and vertebrate retinas⁷ has been reported.

Electrophysiological examinations of more than 100 single and multiple ommatidium preparations have demonstrated inter- and intra-preparation X-ray sensitivity variations in contrast to relatively stable visible light-excitability. Records of single optic axon spike responses to whole lateral eye X-irradiation suggest that the minimal threshold may be low relative to common human exposures. Approximately 0.025 r. is delivered in a routine dental radiographic exposure. Fig. 1 describes the stimulus-response relationship for an X-ray sensitive, dark adapted ommatidium. X-ray parameters were 50 kVp., half-value layer 0.2 mm aluminium. Abscissa, absorbed dose was measured as the incident minus the transmitted dose accumulated during the two-second stimulus. Lateral eye preparation and maintenance have been described elsewhere^{1,5,6}.

It was common to find axons of individual ommatidia which were refractory to X-irradiation doses six log units greater than Fig. 1 threshold and three log unit X-ray intensity variations. The same neural units discharged vigorously during moderate visible stimuli (~10 lux). With less frequency, whole lateral eyes have been tested the optic nerves of which responded with a normal spike output to light flashes but remained largely quiescent during X-irradiation. In these cases it was not possible to record from all optic neurones.

The optic axon potentials in Fig. 2 were recorded simultaneously from two functional unit axons. Light stimulation was provided by an R1131C (Sylvania) glow modulator tube driven by a variable square wave. The stimulus spot diameter was reduced to 75 μ at the cornea. Programmed stimulation began with a 1.7-sec light flash, followed by a 100-sec interval, and then a 4-sec X-ray exposure. A visible test flash was superimposed on the X-ray stimulus. Four records were taken at

Fig. 1. Stimulus-response relationship for X-ray initiated optic nerve unit activity. Intensity of the two-second X-ray flash was varied by target-eye distance. Datum points are the means of four measures. The potentials indicated single unit activity

X-ray intensities intermediate to A and B of Fig. 2. Before A was recorded both receptors were located by the spot of light and it was determined that both axons responded similarly to the standard visible stimulus. Discharges indicative of two axons are present and may be identified by the degree of positive overshoot (downward deflexion). The unit which produced the greater overshoot emitted consistent response patterns to the standard visible test flash although the second light stimulus in each record was superimposed on and preceded by X-irradiation. Its counterpart responded during X-irradiation and more vigorously as the X-ray stimulus intensity increased.

Reports of retinograms and other retinal potentials may be interpreted to support X-ray excitation of the visual cell by a rhodopsin reaction⁷. Rhodopsin has been established as the photopigment of the *Limulus* ommatidium³, but its action spectrum has not been extended into the X-ray band. Dartnall has suggested that 'inadequate' quanta are not absorbed by the rhodopsin chromophore⁸. The X-ray quanta probably exceed the energy required for photochemical activation which becomes a matter of absorption probability in the chromophore.

Fig. 2. Optic nerve axon potentials recorded simultaneously from two functional unit axons. Light stimulation was confined to one ommatidium. The whole eye received X-rays. In A the unit with greater positive overshoot responded to light but was not activated by X-rays which excited the unit axon identified by the smaller positive overshoot. Events in B were similar where X-ray intensity was increased. Some potentials were darkened for reproduction

However, quanta of higher energy than those of the visible band may be absorbed in photostable portions of the rhodopsin molecule¹⁰.

It is difficult to explain consistent X-ray stimulus specificity by rhodopsin bleaching. Direct high-energy quantum interaction with the neural apparatus would account for numerous unexplained reports of X-ray avoidance behaviour in animals¹¹ and sensory phenomena in human beings¹².

Presynaptic Effects of Potassium Ion on the Mammalian Neuromuscular Junction

THE depolarization of motor nerve terminals by the application of a cathodic current increases the frequency of spontaneous miniature potentials (m.e.p.p.s), but under these conditions the number of such quantal units of transmitter released by a nerve impulse is decreased in proportion to the intensity of the presynaptic depolarization¹⁻³. Although the depolarization of the nerve terminal by elevating the potassium concentration also causes an increase in the frequency of m.e.p.p.s, the potentiation in this case continues to develop even after depolarization has reached a maximum^{3,4}. Although equivalent depolarization can be achieved both electrically and chemically, the effects of these stimuli are not entirely parallel, as the quantum content of the end-plate potential is decreased in the first case but is potentiated in the second^{1,2,5}.

Since it is evident that presynaptic depolarization alone does not account for the facilitatory effect of potassium, the question naturally arises as to whether this cation may affect some other specific process in the mechanism of transmitter release. The work recorded here was carried out in order to determine whether the action of potassium could be accounted for by an increase in the probability of stimulus-evoked transmitter release.

Investigations of the effects of potassium on neuromuscular transmission were performed *in vitro* on the rat diaphragm-phrenic nerve preparation as described by Bulbring⁶. Rats of the Wistar strain, unselected as to sex, weighing 200-300 g, were used in these experiments. The left hemidiaphragm with its phrenic nerve intact was removed under acute ether narcosis and immediately immersed in a physiological solution⁷, which was gassed with a mixture of 95 per cent oxygen and 5 per cent carbon dioxide by means of a lift pump system similar to that described by Szekeres and Vaughan Williams⁸. The temperature was maintained at $33^{\circ} \pm 0.1^{\circ} \text{C}$ throughout the experiments.

Resting membrane potentials and transients were recorded by conventional techniques^{9,10}. E.p.p.s and m.e.p.p.s were displayed at high amplification and photographed from one beam of an oscilloscope. To record the depolarization caused by a given concentration of potassium and to be able to reject fibres damaged during electrode placement, the membrane potentials of all fibres were continuously monitored on a second beam, which received signals through a direct-coupled amplifier. End-plate potentials were evoked by stimulating the phrenic nerve with repeated supramaximal stimuli delivered at frequencies of 25 or 50 c/s for 1-2 sec, and recordings were made when neuromuscular transmission was partially blocked either by the combined action of 10 mM magnesium and 1.5 mM calcium, or by curare, present in concentrations of $2-5 \times 10^{-7} \text{ g/ml}$. The addition of magnesium chloride, calcium chloride and potassium chloride was osmotically compensated for by omitting appropriate amounts of sodium chloride from the medium¹¹.

The number of transmitter quanta released by a nerve impulse was estimated in two ways according to the conditions of the experiment. When neuromuscular transmission was blocked with high concentrations of magnesium, the quantum content m of an e.p.p. was determined from the ratio of the mean e.p.p. to the mean m.e.p.p. amplitude. In curarized preparations, the estimate was made from the ratio of the variance to the mean amplitude obtained in trains of impulses¹². The concentrations of magnesium and curare used in the present work so reduced the postsynaptic depolarization by the e.p.p. that correction for non-linear summation was not necessary. The errors introduced by post-synaptic depolarization and the loss of small m.e.p.p.s into base-line 'noise' were neglected, as both factors were small.

When neuromuscular transmission was partly blocked with magnesium, an increase of the external potassium concentration from 5 to 15 mM produced a rise in the spontaneous quantal discharge frequency (m.e.p.p.s) from 5.8 to 20.8 sec⁻¹, and an increase in the mean number of quanta per e.p.p. from 4.2 to 7.2 (Table 1). To determine whether the facilitation of stimulus-linked release resulted from an increase in the size of the available pool of pre-formed transmitter quanta or whether it was due to a greater probability of release by a given impulse, additional experiments were performed with partially curarized preparations. It could be expected that the rate of initial transmitter depletion during a tetanus would increase if only the probability of release were affected, but would decline if the potassium excess had mobilized a greater number of pre-formed quanta or had speeded the reloading of vacated sites. If, on the other hand, the pool of transmitter were simply increased while the nerve impulse

Fig. 1. The effect of potassium ions on the rate of initial transmitter depletion at 33° C. ●, Control solution containing 5 mM K⁺; ▲, high potassium solution containing 15 mM K⁺. Each point represents the average of several fibres plotted as per cent of mean initial end-plate potential amplitude. Stimulation rate 50 c/s

continued to release a constant fraction of transmitter, the depletion rate would remain stable and the absolute number of quanta released by successive impulses would rise.

It can be seen in Fig. 1 that the rate of depletion of transmitter during a tetanus was significantly increased when the potassium concentration was raised from 5 to 15 mM. The absolute number of quanta escaping per initial nerve impulse was nearly doubled by this treatment, the value of m rising from 117.3 ± 18.7 to 249.0 ± 20.2 , and the level of sustained transmitter output, estimated from trains of impulses after an initial rundown, rose from a value of 70.0 to 132.8 (Table 2).

These results indicate that the potassium has at least two direct effects on neuromuscular transmission. It clearly increases the probability of release of transmitter by a nerve impulse and it also raises the number of quanta of transmitter in the readily releasable store.

Prolonged Administration of Atropine or Histamine in a Silicone Rubber Implant

In the use of drugs, it is often desirable to maintain a constant blood and tissue concentration of chemical for prolonged periods. Several attempts to avoid the 'saw-tooth' oscillations of drug-levels that accompany periodic dosing have been reported. Daily injections of histamine in a beeswax repository have been used to develop gastroduodenal lesions in dogs¹. Thompson *et al.*² found that a single intramuscular injection of highly insoluble pamoate salt (C1-501, cycloguamil pamoate) in mice and monkeys was successful as a repository drug against malaria. A constant level of medication, using silicone rubber as a carrier, was attempted by Folkman and Long^{3,4} for cardiac pacemaker drugs and by Powers⁵ in treating experimental malaria and schistosomiasis. We chose to investigate further the practicability of using silicone rubber to effect the slow release of drugs. Atropine and histamine were chosen for the study because they gave diverse but measurable responses, mydriasis in rats and gastroduodenal lesions in dogs.

Atropine base was placed in tubes of silicone rubber ('Medical Silastic 372', 3.140 in. intern. diam. \times 0.236 in. extern. diam.) (kindly supplied by Dow Corning Corp., Midland, Michigan), 3-6 cm in length to accommodate varying amounts of drug. Ends of the tubes were sealed with silicone medical adhesive. These tubes were washed in water, sterilized in benzethonium chloride, 1:750 ('Phemerol', Parke, Davies and Co., Detroit, Michigan) for 24 h, and placed in sterile distilled water for 24 h.

Thirteen treatments consisted of: subcutaneous tube implants of atropine base (powder) at 400, 200, 100, 50, 25, 12.5 and 6.25 mg/rat; implants of empty tubes plus subcutaneous injections of atropine base suspended in aqueous 1 per cent methyl cellulose in doses of 400, 100, 25 and 6.25 mg/rat; 2 carrier control groups: (a) empty tube implants; (b) empty tube implants plus subcutaneous injection of 1 per cent methyl cellulose. Tubes were placed in a subcutaneous channel between the scapulae, and the skin incision was closed with wound clips. The thirteen treatments were assigned to 78 Sprague-Dawley male rats according to a randomized block design with a total of six blocks. The animals were housed, one block per cage, in a room with constant temperature and humidity.

Following implant, daily observations of pupil dilatation were made with an ophthalmoscope without knowledge of individual treatment. The degree of mydriasis was recorded as one of five possibilities. The normal pupil received a rating of 0, and 25, 50, 75 and 100 per cent dilatations were rated +1 to +4 respectively. The values recorded in Fig. 1 represent the number of days each treatment group had a mean response equal to or greater than +1 mydriasis.

Atropine, enclosed in 'Silastic', produced a dose-dependent mydriasis. Duration of mydriasis was longer with the 'Silastic' tube implant than with the atropine injection. For example, at the 100 mg/kg dose-level, the 'Silastic' tube group had mydriasis for twenty-six days while the injected group had only six days of mydriasis (Fig. 1). The control groups had mydriasis for one day which was probably due to their eating animals that had had received a lethal dose of atropine.

Mortality was dependent on mode of administration. There were no deaths among the rats receiving atropine in 'Silastic' tubes. When atropine was injected subcutaneously, 400 mg was fatal to 6/6 rats and 100 mg was fatal to 3/6 rats. Animals which received injections had severe necrosis at the injection site.

Attempts were made to induce gastrointestinal lesions with histamine implants in dogs of mixed sex and breed weighing 8-10 kg. Histamine (Calbiochem, Los Angeles) was placed in silicone rubber tubes or moulded with 'RTV 5392' (Dow-Corning, Midland, Michigan). To

Fig. 1. Duration of mydriatic response in days \pm S.E. to graded doses of injected (stippled bars) and silicone encapsulated (plain bars) atropine in rats.

form the mould, 250 mg histamine base was triturated with 5 c.c. of the liquid silicone rubber, drawn into a plastic syringe and allowed to vulcanize. The plastic syringe was broken to remove the mould. All implants were sterilized as already described here. The tubes, a mould, or a tube plus a mould were implanted subcutaneously between the scapulae. At autopsy the stomach and duodenal areas were examined macroscopically for lesions. The results are shown in Table 1.

Table 1. ABILITY OF VARIOUS FORMS OF HISTAMINE IMPLANTS TO INDUCE LESIONS ON THE GASTRO-DUODENAL AREA OF DOGS

No. of dogs	Method of administration	Amount of histamine (g) per implant	No. of implants	No. of days between first implant and autopsy	Lesions
6	Tube (T)	1-2	1	46-68	Neg.
2	T	2†	1	63	Neg.
2	T	0.5	5*	42	Perforated duodenal
2	Mould (M)	0.5	1	42	Neg.
1	T+M	0.5-T+0.25-M	5*	42	Neg.
2	T+M	0.5-T+0.25-M	4-5*	30-42	Antral and duodenal

* The implants were placed subcutaneously at intervals of one week and autopsy performed one week after the final implant.

† Dose divided among 4 tubes, and implanted subcutaneously in a single operation.

Six dogs received implants of a single tube containing 1 or 2 g of histamine; two dogs received 2 g of histamine divided among four tubes. None of these animals showed gross changes in the appearance of the gastrointestinal mucosa when autopsied 46-68 days after implant (Table 1). Weekly implants of single tubes containing 500 mg histamine into two dogs caused perforated duodenal lesions within 42 days.

The implant of a histamine mould gave negative results. Weekly implants of a tube plus a mould produced lesions in two of three dogs. One had multiple antral and duodenal erosions, the other developed one large and one perforated duodenal lesion (Table 1).

Histamine repositories were evaluated for their effects on gastric secretions in dogs prepared with denervated fundic pouches. Single tubes of 500 mg of histamine base were subcutaneously implanted into three dogs. Secretions and acid outputs were monitored periodically during

the following eight days and compared with pre-implant rates. In a second test, a mould of 250 mg histamine base in 'RTV 5392' was implanted into each of two dogs. Secretions were monitored for 12 days. Neither the tubes nor the moulds had any prolonged marked effect on secretion. The moulds caused a slight increase in secretion on the first day only, probably due to surface-trapped histamine.

Each of four dogs was implanted subcutaneously with four 'Silastic' tubes containing 500 mg histamine (2 g total). One dog showed no change in secretion for 21 days. The second dog had a slight increase in secretion from day 7 to day 37 which returned to basal level. The third dog had an increase in secretion by the 13th day. When killed on the 19th day, numerous large craters were found in the antrum. The gastric pouch and duodenum were normal in appearance. The fourth dog had an increase in gastric secretion by the 15th day. By the 21st day, the animal was losing weight, appeared dehydrated, and had several clonic convulsions. No lesions were found in the gastrointestinal tract.

Like other drugs^{3,4}, atropine encapsulated in a 'Silastic' jacket can exert a slow and prolonged biological response. The lack of effect after a single histamine 'Silastic' tube implant on lesion production or sustained gastric secretion invalidates this type of implant for inducing experimental lesions in dogs. The level of histamine needed to induce lesions or maintain gastric secretion may be critical and cannot be attained by a single implant. The weekly histamine implants did induce gastrointestinal lesions in 4 out of 5 dogs. This type of implant regimen was not tested for its effects on gastric secretion. Chemical determinations will be required to confirm drug-levels in tissues resulting from a repository implant.

A major advantage in using silicone rubber as carrier is that the 'encapsulated' drug can be easily removed from the animal which provides constant control over the duration of exposure to the drug. Waitz *et al.*⁶ demonstrated a similar control with a dialysis bag placed in the peritoneal cavity of rats.

Facilitation as a Function of Temporal Spacing of Stimuli in Intracranial Self-stimulation

THE time interval between successive stimuli has been shown in a variety of situations to be crucial for the amplitude of response. For example, at certain intervals, the earlier stimulus may increase the amplitude of the response to the second stimulus. Such a phenomenon is known as facilitation, and has been demonstrated at the neural level, for example, by Lloyd^{1,2}.

In the experiment to be reported here, the time between two successive trains of electrically rewarding stimuli was varied to assess the effects of temporal spacing between them on a threshold of lever pressing.

The subjects were three male albino rats of the Sprague-Dawley strain, weighing about 250 g at the time of operation. Monopolar stainless steel electrodes, insulated except for 0.2 mm at the tip, were implanted. The co-ordinates aimed for were A 3.0, L 0.8, H 3.2 (Nos. 7 and 21) and A 2.5, L 1.0, H 3.2 (No. 38) according to DeGroot's atlas³.

Fig. 1. The curves show how the threshold for the rewarding effect of intracranial stimulation increases as a function of separation of two 0.1-sec bursts of stimulation. The two uppermost curves for Nos. 38 and 7 show the result when the second train occurs 0.9 sec after the lever press. The other curves show the result when the first burst occurs immediately after a lever press is made. The two trains were only available once per second in both conditions. Δ - - - Δ , No. 38; \circ - - \circ , No. 38; \blacktriangle - - - \blacktriangle , No. 7; \square \square , No. 21; \bullet - - \bullet , No. 7.

The rats were trained to press a lever in a Skinner box. A press delivered a 60-c/s large-amplitude stimulus lasting for 0.5 sec. The next stimulus was not available until 0.5 sec after the termination of the previous stimulus. The intensity of the 60-c/s stimulus was so adjusted that when the stimulus was disconnected after a session lasting one minute, the animal would continue pressing for well over a minute. As the method used has already been described^{4,5}, it will be only briefly recapitulated. Short training sessions were given at the end of each of which the current was disconnected. Such training continued until the rat left the bar within a few seconds after the current was switched off. When such training was complete, a session lasting one minute, with 60-c/s stimulus at the high intensity previously used, was followed by a test period of a further minute. During the test minute, the animal could only obtain, if it pressed, a certain intensity of two 0.1-sec trains of 60 c/s. (It is found that below a certain intensity the animal will act as if the current had been disconnected and above this level will tend to keep on pressing to obtain intracranial stimuli.) The criterion taken for the cessation of pressing (behaviour on the part of the animal as if no stimulation was obtained) was the execution of no responses at all for a continuous 30-sec period during the test minute. Reward threshold was then taken to be the step in intensity of the two 0.1-sec trains just above that at which the rat met the criterion of cessation of bar pressing. The stimuli which the rat could obtain during the test periods consisted of two 0.1-sec trains of 60 c/s separated by intervals of 0.1, 0.2, 0.3 and 0.4 sec. The maximum rate at which such train couples could be obtained was once per second.

The experiment was run under two main conditions. In one condition, the first train occurred as soon as the animal pressed the lever, at the beginning of the one-second interval which had to elapse before a further stimulus couple was obtainable. In the second condition (used to control for differential average delay of reinforcement with different intervals between the two 0.1-sec trains with Nos. 7 and 38) the last pulse was always

given at the end of the second after the animal had pressed. In this way the average length of delay of reinforcement after a response was now longest for the 0.1-sec interval between trains, whereas in the first condition when the first train began at the beginning of the lever press, it was the shortest. A descending method of limits was used and the order of intervals (0.1-0.4 sec) was presented randomly from session to session.

The control of the timing of stimuli was achieved by using 'Digibit' logic panels. The 60-c/s stimulus was connected to the animal through a 'Variac' transformer and an isolation transformer. A 200-kohm resistor was placed in series with the electrodes. The stimulus to the animal was monitored on a 'Tektronix 502' oscilloscope.

The results are presented in Fig. 1. An analysis of variance was performed on the results of each individual animal in each of the two conditions separately. All the results indicate a linear trend (of current against interval between trains), the lowest level of significance being at the 0.01 level of confidence, no other effects being significant at this level.

It seems that the threshold for the rewarding effects of intracranial self-stimulation decreases the closer the temporal spacing of two identical stimulus trains. Though at present the relation of such a phenomenon to neural facilitation cannot be inferred with certainty, it seems most likely that the facilitation here observed occurs in the neural system subserving rewarding intracranial stimulation. The length of interval over which facilitation occurs is in excess of 0.4 sec. However, it is difficult to compare such a figure with others obtained under other conditions.

IMMUNOLOGY

A Specific Agglutinin in the Snail *Otala (Helix) lactea*

BLOOD group specific agglutinins (lectins) were found some years ago in various plants¹⁻³. Such substances have been found also in invertebrate animals⁴, the most recent report being that by Johnson⁵ of a weak anti-A₁ in the clam *Saxidomus gigarticus*.

We have found that the expressed body fluids of the land snail, *Otala lactea*, contain a powerful and specific anti-A agglutinin (titre for A₁ erythrocytes 8,000, for A₂ 2,000). This agglutinin, even undiluted, does not clump group O or B cells at all. It precipitates promptly and specifically with blood group A substance⁶ prepared from hog gastric mucin, and the supernatant from a mixture of these two reagents in optimal proportions contains no detectable A or anti-A activity.

We plan to investigate this interesting substance further; we already have some reason to think that this new anti-A agglutinin may prove useful in distinguishing homozygous AA from heterozygous AO erythrocytes⁷.

Differentiation between Cytophilic Antibody and Opsonin by a Macrophage Phagocytic System

OPSONIC antibody by combining specifically with antigen facilitates ingestion of that antigen by leucocytes. Recently, a cytophilic antibody has been described which becomes attached to mammalian cells *in vitro* in such a way that antigen is specifically adsorbed^{1,2}. The investigation reported here was made to compare the ability of these two types of antibody to potentiate phagocytosis.

Groups of 30 to 40 mice were injected with bovine γ -globulin (BGG) or bovine plasma albumin (BPA) in Freund's complete adjuvant, or *Escherichia coli* somatic polysaccharide antigen. Antisera from each group were pooled. The γ - and β -globulins were precipitated by sodium sulphate³, purified on DEAE cellulose with a phosphate borate buffer to obtain the γ -globulin⁴, and divided into sub-fractions by electrophoresis once or twice in agar gel⁵, the extent of the separation in the gel being detected by rabbit anti-mouse globulin.

Each sub-fraction was brought to the same protein concentration of 0.25 mg/ml. They were tested for the following antibody activities:

(1) Agglutination of sheep red cells to which BGG and BPA were attached either by the tanned red cell technique⁶ or by the *bis*-diaz benzidine coupling method⁷, and to red cells treated directly by the polysaccharide⁸.

(2) Sensitization of the skin to anaphylaxis in mice⁹ (PCA).

(3) Adsorption of antigen by macrophages treated with cytophilic antibody (CT). The macrophages were in monolayers obtained by washing the peritoneal cavity of a mouse with Hanks's balanced salt solution, and diluting the suspension in Hanks's containing 10 per cent normal mouse serum from which any specific antibody had been removed by adsorption in the cold with red cells coated with the specific antigen by *bis*-diaz benzidine. Monolayers were formed by adding the suspension to glass slides for 1 h at 37° C. After washing they were treated with the antibody preparations for 0.5–1 h, washed twice for 30 min, and exposed for 1 h on a rocker at room temperature to a 0.5 per cent suspension of the antigen-coated red cells. Monolayers treated with *E. coli* antisera were also exposed to a suspension of the heat-killed organisms. After washing, the slides were examined under phase contrast. In a positive reaction large numbers of red cells or organisms became adherent to the macrophages; in a negative reaction nearly all the antigen particles remained evenly dispersed between the macrophages.

(4) Opsonization to phagocytosis. Opsonin was detected by exposing the antigen particles at 37° C to the antibody preparations for 1 h, washing them and adding the sensitized particles to the monolayers maintained at 37° C. The result was read after 0.5 and 1 h. An antibody preparation was considered to contain opsonin when the

Fig. 1. Antibody activity to protein antigens in fractions of mouse γ -globulin

number of macrophages ingesting antigen was at least twice that in a test of the same antibody preparation adsorbed with the appropriate antigens.

After each test for CT antibody and opsonin, a duplicate slide of each was treated with normal mouse serum adsorbed in the cold to remove antibody to sheep cells and the specific antigen, and also adsorbed by macrophages to remove non-specific CT antibody. This provided complement-like factors which increased the number of macrophages ingesting antigen in both tests.

Two globulin fractions $\gamma 1$ and $\gamma 2$ were separated¹⁰, and each divided into 4 sub-fractions. The various antibody activities to protein antigens in all fractions were presumably those of 7S globulins since the potencies of the fractions were unchanged by treatment with 0.09 M mercaptoethanol pH 7.0.

All 8 sub-fractions of anti-BGG and anti-BPA contained agglutinins (Fig. 1). Antibody sensitizing skin to passive cutaneous anaphylaxis (PCA) was confined to 3 of the $\gamma 1$ fractions, two of which contained no cytophilic antibody (CT), thus confirming the report that cytophilic antibody does not sensitize to PCA².

Opsonin and CT antibody to BGG and BPA were both present in 3 of the $\gamma 2$ sub-fractions, but one $\gamma 1$ sub-fraction contained only CT antibody, and one $\gamma 2$ sub-fraction only opsonin. It was possible to remove selectively the CT antibody from fractions containing both by adsorption with macrophages or chopped whole mouse spleen, whereas adsorption with antigen-coated particles removed both types of antibody.

CT antibody was detectable only on macrophages. There was no adherence to lymphocytes, polymorphonuclear leucocytes or kidney epithelium, which therefore do not take up CT antibody; even 97 per cent pure suspensions of lymphocytes failed to adsorb it. The uptake of cytophilic antibody by cells separated from whole organs^{1,2,11} may be a reflexion of their content of macrophages, though uptake by mast cells has been reported and also red cells¹¹.

The proportion of macrophages ingesting protein-coated antigen particles in tests with CT antibody and opsonin is recorded in Table 1. More macrophages ingested antigen after treatment with cytophilic antibody than those treated with a similar fraction of normal serum. If serum adsorbed free of specific antigen and unrelated CT antibody was added after the antigen particles had adhered to the macrophages, ingestion was greatly increased.

In summary, the properties of cytophilic antibody specific for the proteins are that it is adsorbed by living

Table 1. PROPORTION OF MACROPHAGES, OUT OF 200, INGESTING PROTEIN ANTIGEN COATED ON RED CELLS IN TESTS WITH CYTOPHILIC (CT) ANTIBODY AND OPSONIN

	Macrophages, prior treatment	Test with	Mean % phagocytosis
(1)	Nil	Antigen	20
(2)	Normal serum protein	Antigen	17
(3)	Nil	(Antigen + CT)	28
(4)	CT antibody	Antigen	58
(5)	Opsonin	Antigen	19
(6)	Nil	(Antigen + opsonin)	92

macrophages or those gently killed by drying or freezing, but not by lymphocytes or polymorphonuclear leucocytes. Antigen treated with CT antibody, even in antibody excess, is not adsorbed to normal macrophages. Adsorption of CT antibody is blocked by previous treatment of the macrophages with CT antibody of unrelated specificity, and antigen particles adherent to treated washed macrophages may be eluted by addition of serum containing an unrelated CT antibody. Macrophages treated with CT antibody ingest more antigen particles than cells treated with similar fractions of normal serum. On the other hand, opsonin is not adsorbed to macrophages or polymorphonuclear leucocytes, but combines with antigen particles so that large numbers are ingested by both types of cell.

Analysis of *E. coli* antisera yielded a slightly different result. The CT antibody present in the intact serum was apparently inactivated during salt fractionation and separation on DEAE, and it was destroyed by mercaptoethanol. It appears, therefore, to be a 19S macroglobulin. It promoted ingestion of killed *E. coli* by the macrophages, but not ingestion of red cells coated with the somatic polysaccharide though these adhered to all the treated macrophages. It was clearly distinct from the opsonin which was stable to the fractionation procedures and unchanged by mercaptoethanol. This is similar to the finding of cell-bound 19S antibody and free 7S antibody in mice infected with attenuated *Salmonella typhimurium*¹².

The first stage of phagocytosis is contact of the particle with the surface of the phagocyte. Opsonic antibody changes the surface of the antigen particles so that they are more readily ingested by macrophages and polymorphonuclear leucocytes. Cytophilic antibody is a poor opsonin when added to free antigen, but it increases the speed and number of antigen particles becoming adherent to macrophages; as a result some of the particles are ingested. It is possible that *in vivo* cytophilic antibody sensitizes the macrophages lining sinusoids of lymph nodes, spleen, liver or other organs, so that foreign material, for example, bacteria or their toxins, are more rapidly removed from the circulation. Thus its probable function is to act as a 'cell-bound' (or 'cell-fixed') opsonin.

BIOLOGY

Signal Value of the Genital Tassel in the Male *Tilapia macrochir* Blgr. (Pisces: Cichlidae)

In some of the mouthbrooding *Tilapia* species, during breeding season the males develop highly conspicuous appendages on their genital papillae. These are long bifid filaments which are either fringed or festooned with colourful blobs of tissue. The biological significance of

Fig. 1. Female nibbling at the male's genital appendage. The sperm thread is clearly visible at the lower left.

these 'genital tassels' is still obscure, although field-studies have indicated that they play a part during spawning activities^{1,2}. Careful observations of *T. macrochir* in our laboratory tanks have revealed some interesting details. The genital tassel of the male in this species consists of two bright white threads fringed with a few smaller threads of the same colour (Fig. 1). In a fully grown male of 30–40 cm the appendage reaches a length of 5 cm. It acts as a special signal which is presented to the 'ripe' female during courtship and spawning, and assures fertilization of the eggs in the following way:

(1) When a female is ready to spawn she enters a male's spawning pit. After some courtship movements, the male starts to drag his tassel over the bottom of the pit and up the surrounding wall. On top of the wall, he presses his genital papilla to the ground and then rises and swims tail-first back over the female across the spawning pit (Fig. 2). Simultaneously he ejects from his genital opening a long, 0.5-mm-thick whitish thread which sticks by its free end—for a very short time only—to the spot where he stopped dragging his tassel, and a few seconds later the threads drift away in the water.

(2) The female follows the male and grasps the spermatophore-like thread between her lips and inhales it. Very often she not only takes the thread but also the whole genital tassel, or parts of it (Fig. 1), into her mouth. She does this even before she has started to lay eggs and later fairly regularly following each single spawning act. She repeatedly drops some ten eggs, often from a rather peculiar position, namely, standing obliquely head-down several centimetres over the pit. She does not, however, immediately snap up the eggs into her mouth, but will usually follow the tassel-dragging male once more.

(3) The sperm-thread which the male ejects does not normally meet the eggs immediately, since it drifts away from the pit while the eggs are still laying there. The female, therefore, has to snap up the thread to bring it into contact with the eggs, which she starts to gather into

Fig. 2. Movements of the fertilizing male ejecting the sperm thread

her mouth immediately afterwards. The solid sperm mass of this species seems rather favourable in this situation since it is not blown out through the female's gill-openings as readily as would be a loose cloud of milt-fluid found in most of the other *Tilapia* and cichlid-species.

(4) The tassel directs the female's attention to the male's genital opening just before the sperm is ejected, and hence minimizes the danger of the 'spermatophore' being lost. This seems to be the main function of the tassel, which in *T. macrochir* resembles a large number of whitish sperm-threads and, indeed, is treated by the female as such. I hope to investigate this further with dummy experiments.

From the point of view of comparative zoology, it would be interesting to know whether one of the many related species has proceeded still further to true spermatophores. The whole spawning procedure of *T. macrochir* offers phylogenetically important parallels to that of the *Haplochromis*-species in which fertilization of the eggs also takes place within the mouth of the female, and is ensured by egg-dummies painted on the male's anal fin, which are treated by the female as real eggs³⁻⁵.

Emission of Feulgen-positive Particles during the *in vitro* Maturation of Toad Ovocytes

THERE has recently been a growing interest in the possible role and localization of cytoplasmic deoxyribonucleic acids (DNA) in amphibian eggs. Our own observations¹⁻³ suggest that large amphibian ovocytes contain at least two different kinds of DNA: a major constituent, which is bound to the yolk platelets and is probably a reserve material of low molecular weight, and a minor component which surrounds the germinal vesicle of the larger ovocytes: the latter is relatively resistant to acid hydrolysis and might originate from the nuclear sap which, as shown by Izawa *et al.*⁴, contains appreciable amounts of DNA. It is of interest to examine the distribution of DNA in ovocytes which, as a result of a treatment with pituitary hormones, undergo maturation (breakdown of the germinal vesicle which results in the mixing of the nuclear sap and the cytoplasm). In fact, some 25 years ago, I examined⁵ DNA distribution during the spontaneous maturation of frog (*Rana temporaria*) ovocytes: it was observed that the breakdown of the germinal vesicle is followed by the appearance of small Feulgen-positive

granules which lie close to the chromosomes. Their origin and fate could not be established.

More precise observations have now been made on ovocytes the maturation of which had been obtained *in vitro*, following the technique of Dettlaff *et al.*⁶. Large ovocytes of *Bufo bufo* or *Xenopus laevis* were placed in 15 ml. of Ringer's solution containing 4 crushed pituitaries of the same species. They were fixed in Zenker every 15 min; alternate sections were stained with methyl green-pyronine and with the Feulgen reaction. Four experiments were made with *Bufo* and one with *Xenopus*. In all of them but one (*Bufo*), *in vitro* maturation was successful. Two experiments with *Triturus* and one with *Pleurodeles* failed: the breakdown of the germinal vesicle was still incomplete after a treatment with 9 pituitaries for more than one day. Our observations are thus, for the time being, restricted to the Anurans.

In both *Bufo* and *Xenopus*, after a 3-h hormonal treatment, the nuclear membrane shows numerous invaginations. They stain strongly with pyronine and appear on the vegetal side. At the same time, the nuclear sap becomes more hydrated and basophilic. The chromosomes are condensed, while the nucleoli, which have moved towards the animal side of the germinal vesicle, begin to shrink and to lose their basophilia. These changes in ribonucleic acid (RNA) distribution might correspond to the synthesis of small amounts of heterogeneous RNA observed by Brown and Littna⁷.

A couple of hours later, the vegetal side of the nuclear membrane is completely broken down; the nuclear sap is now fibrous in appearance and looks like a giant spindle; it carries the strongly Feulgen positive chromosomes. At the limit of the 'spindle', where remnants of the nuclear membrane can still be seen, very small Feulgen-positive particles can be observed. They are never in visible contact with the chromosomes and are very numerous (about 100).

Later on, these fine particles coalesce to form larger spherical Feulgen-positive bodies, which surround the spindle and the chromosomes. Both bodies and spindle move together towards the animal pole. Finally, after a 7-8-h treatment with the pituitary hormones, one or two large bodies, which stain intensely with Feulgen, can be observed in the cortex of the ovocyte, at a short distance from the maturation figure (Fig. 1). Judging from the intensity of the Feulgen reaction (which is negative after treatment of the sections with deoxyribonuclease), these cortical bodies must contain much more DNA than the chromosomes.

The origin and fate of these cortical Feulgen-positive spheres (which can no longer be seen in ripe unfertilized eggs) will remain enigmatic so long as combined autoradiographic experiments (incorporation of thymidine) and electron microscopy observations have not been performed. Although it is impossible for the time being to exclude a chromosomal or nucleolar origin, the most likely interpretation of our observations is that the

Fig. 1. Cortex of a *Bufo bufo* ovocyte undergoing *in vitro* maturation after 7 h. Arrow on the left, maturation spindle and chromosomes; arrow on the right, Feulgen-positive sphere

Feulgen-positive granules and spheres arise from the nuclear sap, when it mixes with the cytoplasm. If so, they would have the same origin as the DNA found around the germinal vesicle in very large *Triturus* oocytes².

It can be concluded from these observations that, in all anuran species examined (*Rana*, *Bufo*, *Xenopus*), mixing of the nuclear sap with the cytoplasm, as a result of an *in vivo* or *in vitro* hormonal treatment, leads to the production of extra-nuclear DNA, which ultimately moves into the cortex of the egg. This cortical localization of the Feulgen-positive spheres might be very significant, since we know the extreme importance of the dorsal cortex (grey crescent) for morphogenesis (gastrulation, neural induction)⁸. As I have pointed out recently⁹, the dorsal cortex of the fertilized egg must, ultimately, control the activation (or de-repression) of certain genes in the dorsal lip of the blastoporus (organizer). It is conceivable that this de-repression might be mediated, as suggested recently by Frenster¹⁰, by a DNA-like RNA, which should be, in the present case, synthesized on this cytoplasmic DNA template. Very recent experiments by Curtis¹¹ suggest that the dorsal cortex of *Xenopus* eggs possesses its own heredity: his results can only be understood if one assumes that it contains particles capable of independent replication. The presence of DNA, originating from nucleocytoplasmic interactions during maturation, in the cortex might perhaps account for these curious observations. Another attractive possibility is that the cortical DNA might play a part in the determination of the germ-cells, since it is known, from the work of Blackler¹², that ultra-violet irradiation of the vegetal pole in fertilized eggs results in sterility. Much more work is obviously needed before the function of the 'cortical DNA' becomes clear.

This work was carried out under contract Euratom-U.L.B. 016-61-10 ABIB.

Wheel-running Preferences of *Peromyscus*

THE bases for the strong predilection of captive and domestic rodents for wheel-running are not fully understood. It is clear that wheel-running provides a relatively strenuous form of muscular exercise which is not otherwise available to confined animals. In addition, the acts of manipulation and control of the movements of an activity wheel may be rewarding to rodents, quite independently of exercise¹. Rodents also find it rewarding to run motor-driven activity wheels which they start and stop by pressing levers¹.

That the attractiveness of wheel-running cannot be attributed solely to the fact that it is an outlet for vigorous muscular activity is shown by the finding that rodents in extensive enclosures which contain complex burrow-simulating mazes and hundreds of feet of linear runways frequently spend much of their time running an activity wheel². The present study grew out of the observation that deer mice also learn to run activity wheels shaped

into squares, triangles, ellipses, etc., even when round wheels are also available³.

A 15×15×14 in. enclosure was constructed of 'Perspex' and hardware-cloth, containing four adjacent coaxial activity wheels made of 3-in. strips of 1/8-in. mesh hardware-cloth. Dual ball-bearing mountings gave all wheels a very low frictional torque. The 'round smooth' and 'large round' wheels were 10 in. in diameter, the former containing an inner lining of acetate film. The 'small round' wheel was 6 in. in diameter, and the 'square' wheel was 7 in. square. The highest rates at which these wheels were run were: smooth round, 84; large round, 90; small round, 138; and square, 114 r.p.m. Wheel revolutions were sensed by a microswitch actuated by 1/4-in. ball bearings on the end of a half-inch metal strip forming a spoke of the wheel. The spokes extended through slots in the 'Perspex' roof of the enclosure, on which the microswitches were mounted.

Two litters of young captive-born canyon mice, *Peromyscus crinitus* (litter 1, 8 weeks old, 2♀, 1♂; litter 2, 7 weeks old, 3♂), and 2 old males, captured 3 years previously, were selected for study. The old animals had had experience running motor-driven and freely turning wheels 2½ years earlier (see ref. 1). The old males were studied individually, whereas the 3 animals in each litter were studied in consort.

Simply making activity wheels available to inexperienced *Peromyscus*, even for several weeks, does not necessarily give information concerning the preferences of experienced animals for the different types of wheels, because *Peromyscus* generally tend to be conservative in their behaviour⁴. Thus, whichever wheel an animal learns to run first often monopolizes its subsequent activity—the other wheels virtually being ignored. The following programmes were adopted to ensure that the animals would become experienced in running all the wheels. Using individual males, all 4 wheels were made available at first (phase 1) until a constant pattern of wheel running was established and maintained for 2–4 days. The wheel in which the most revolutions were run (which generally was the one in which the most time was spent running) was then locked, and the experiment was continued with 3 wheels unlocked (phase 2) until a new constant pattern was established and maintained for 2–4 days. The favoured wheel of the 3 was then locked (phase 3) and, afterwards, the favoured wheel of the remaining 2 (phase 4). After the animal had learned to run the last unlocked wheel, the wheel of third choice was unlocked until a constant pattern of running was established and maintained for 2–4 days (phase 5). The wheel of second choice was then unlocked (phase 6) and, finally, the wheel originally of first choice was unlocked (phase 7). Phase 7, in which all 4 wheels were available to the experienced animal, lasted at least 6 days. The programme with groups of 3 young animals in consort differed solely in that only 2 wheels were locked (that is, phases 4 and 5, being unnecessary, were omitted).

Running comparisons were made on the basis of average numbers of revolutions run in the different wheels per night. Time spent running, although not measured, is roughly proportional to the product of the number of revolutions run and the circumference of the wheel (7π for the square wheel). The values plotted in Fig. 1 are the averages for the adapted running of the last 2 or more days of each phase. A bright-dim light cycle (L:D 14:10) was used. Recording methods and other experimental conditions have been described elsewhere^{1,2}.

In phase 1, animal 20 ran the large round wheel almost exclusively (13,202 revolutions). When this wheel was locked it preferred the round smooth wheel (21,284 revolutions). In phase 3 it ran 28,679 revolutions in the square wheel and only 5,610 in the small round wheel (Fig. 1). With only the small round wheel unlocked (phase 4) it ran 43,051 revolutions. When the square wheel was unlocked in phase 5 the animal resumed its preference for it (38,905 compared with 7,167 revolutions) and maintained this

Fig. 1. Wheel running by canyon mice during the programmes described in the text. The figures for days at the top of each data plot refer to the total durations of the programmes

preference in phases 6 and 7. Thus, although the square and small round wheels were not run in phases 1 and 2, they became the wheels of preference in subsequent phases, with the square wheel very much favoured in phases 5 and 6 (Fig. 1). Animal 25 ran much less than animal 20. It preferred the square wheel in phase 1, the large round wheel in phase 2, and the small round wheel in phase 3. It returned to the small round wheel in phase 5, maintained this preference in phase 6 and showed a slight preference for the large round wheel in phase 7.

The 2 groups of young litter mates showed identical sequences of wheel-running preferences (Fig. 1). In phase 1, the order of preference was: large round, smooth round, and square; the small round wheel was more or less ignored. In phase 2 the square wheel was preferred, with some running of the small round one. In phase 3, the small round wheel was preferred to the smooth round one. The preference for the square wheel persisted when it was unlocked (phase 6), but the smooth round wheel now was run much more than the small round wheel. Finally, phase 7 saw a return to running the large round wheel, which had been preferred in phase 1, but the square wheel remained the preferred wheel.

The results of this exploratory study suggest that: (1) although canyon mice may not run certain activity wheels at all when several types are available, none the less they can learn to run these wheels with great facility; (2) the preferences that are established by giving inexperienced animals a choice of several different types of activity wheels usually differ from those of the same animals after they have had experience in running all of the wheels; (3) a wheel with a hardware-cloth surface is preferred to one with a smooth surface; and (4) experienced animals may prefer a square wheel to a round one.

The implication that can be drawn tentatively from the generally slight to marked preference of experienced animals for a square wheel is that confined wild rodents tend to select forms of exercise that require quick reflex actions and split-second timing and co-ordination of movements (running the square wheel required jumping at the

corners at rates up to 9 times per second) in preference to forms in which vigorous muscular activity is the primary requirement. In view of these findings, it appears that round activity wheels may not be the most suitable type for use in studies of confined wild rodents. Experiments designed to explore these implications further with larger numbers of animals of several species are in progress.

Methylcholanthrene Carcinogenesis influenced by Vegetable Extracts

A GROUP of 700 three-month-old male mice received subcutaneous injections of 0.1 mg methylcholanthrene in benzene and were then observed for the appearance of tumours for 120 days. The injected mice were divided into four groups which were fed differently.

Group I, the controls, were fed on our standard ration of oats added to maize groats boiled in milk, to which cod liver oil, linseed oil and a polyvitamin preparation were added.

Group II received no raw vegetable food from the day of birth. In place of oats they received bread boiled in milk; their litter of beechwood shavings was sterilized in the autoclave and the complete destruction of enzyme activity in food and litter was confirmed by testing for catalase, which was always absent.

Group III were treated similarly except that they were deprived of vegetable food only from the day of injection.

Fig. 1. Symptom of virosis on leaves of *Nicotiana glauca* (light green mosaic) after treatment with aqueous-extract of oats and the seeds of its usual weeds (*Vicia* sp., *Brassica rapa*, *Agrostemma githago*, *Cirsium* sp.).

Fig. 2. Symptom of virosis (malformation) on the leaves of hybrid tomato provoked with aqueous extract of oats and the seeds of its usual weeds (*Vicia* sp., *Brassica rapa*, *Agrostemma githago*, *Cirsium* sp.)

Group IV were fed like Group I, but given subcutaneous injections of 0.1 ml. 'vegetable extract' twice weekly for six weeks.

The 'vegetable extract' was prepared as follows: 10 g oats was ground to powder, and 100 ml. distilled water added. After standing 1-2 h it was centrifuged for 1 h at 4,000 r.p.m., and the supernatant filtered through a Seitz EK filter. This extract contained a number of plant viruses, since on testing in tobacco, tomatoes and beans characteristic changes occurred (Figs. 1 and 2).

Table 1. EFFECT OF FRESH AND AUTOCLAVED VEGETABLES ON FREQUENCY OF METHYLCHOLANTHRENE-INDUCED TUMOURS IN MICE

Group	No. of animals at start of experiment	No. of animals developing tumours	No. of animals surviving to 120 days without tumours	Total No. of animals completing experiment	χ^2
I	300	(95-83)	108	192	300
II	100	(31-62)	11	88	99
III	150	(46-95)	27	120	147
IV	150	(47-60)	76	73	149
Total	700	222	473	695	86-57

Total $\chi^2 = 86.57$. $P \leq 0.001$.

The results are given in Table 1. It is clear that this vegetable extract enhances, whereas a diet free from raw vegetable materials depresses, the carcinogenic activity of methylcholanthrene. Is it the plant viruses which are the cause of this difference?

ANATOMY

Sex Differences in the Rate of Tissue Regeneration in the Rabbit's Ear

It has been found that when wounds are made through the full-thickness of the pinna of the rabbit's ear, and tissue of area 1 cm² is excised (Fig. 1), the tissue deficit is almost completely made good within 98 days, though a small hole always remains (Fig. 2). This entails the regeneration of relatively mobile dorsal skin, elastic cartilage, connective tissue, nerve fibres and immobile

Fig. 1. Appearance of the inside of the ear following removal of a full-thickness portion 1 cm x 1 cm in area

Fig. 2. Appearance of the ear after 98 days. A small central hole remains, but the deficit has otherwise been made good

ventral skin. Furthermore, the process takes place significantly faster in males than in females. It has been reported elsewhere that if either skin¹ or cartilage² is removed from the rabbit's ear it regenerates, the skin completely and the cartilage partially. The replacement of full-thickness deficits has not, however, been reported.

Tissue of area 1 cm² was removed with a specially designed punch from the ears of 30 rabbits (18 male and 12 female) under 'Nambutal' anaesthesia. Care was taken to avoid major blood vessels. Photographic records were kept of the progress of regeneration, the ears being photographed every 7 days. The areas of (a) the central hole, and (b) the zone bordered by the old ventral skin, were calculated from projections of the transparencies on to graph paper by outlining the areas and counting the enclosed squares. The area of the new tissue (a measure of the amount of growth) was determined by subtracting (a) from (b). The amount of contraction (the process whereby the size of the initial deficit is altered by movements of the old adjacent skin) was obtained by subtracting (b) from the initial deficit area. All measure-

Fig. 3. Histograms showing variation in growth of the regenerate in male (a) and female (b) animals

ments of growth and contraction were expressed as percentages of the initial deficit area.

By 49 days there was a difference of 18 per cent between the areas of the regenerate in males (85 ± 2 per cent) and in females (67 ± 6 per cent); this difference was found to be highly significant ($P < 0.005$). The data on which this was based are given in Table 1 and illustrated in Fig. 3. The difference between contraction in males (3 ± 3 per cent) and in females (1 ± 5 per cent) was not found to be significant ($P > 0.3$). It is possible that the regeneration

rate is influenced by androgens. Although in large doses they inhibit the production of granulation tissue^{3,4}, most indications are that they promote reparative processes⁵⁻⁷. This may explain the faster rate found in males. Investigations into this possibility are now in progress.

The rabbit's ear provides a useful material for the investigation of mammalian tissue regeneration. Its flatness and position facilitate the keeping of photographic records of the progress of regeneration from which one parameter of this process, surface area, can be measured accurately. It is thus possible to make quantitative observations of mammalian tissue regeneration over a period of time without causing further trauma which would naturally interfere with the process. It also provides an opportunity to study quantitatively the effects of mechanical and metabolic interference on mammalian regeneration at the tissue level.

We thank the Endowments Committee of Guy's Hospital for a grant towards the expenses of this investigation and the Department of Medical Illustration, Guy's Hospital, for the preparation of the illustrations.

Possible Role of Neuroglia

In a recent communication¹, Hertz has postulated an impulse transmission system in which "potassium ions, which have been lost from one nerve cell during its activity, are transported through neuroglia cells to the outer surface of another nerve cell, which is then depolarized and stimulated; that is, a neuronal-neuroglial-neuronal impulse system". For such a system to operate, the neuroglia cells should bear an appropriate topographical relationship to the nerve cells and should have a capacity for active ion transport; for the pathways to be selective there should be no significant diffusion of potassium ions between cells. Hertz has given good supporting evidence for the second premise, the capacity of glia cells for active ion transport; but the first and third require examination.

The direct synaptic connexion between nerve cells and glia cells which Hertz mentions was described by Scheibel and Scheibel on the basis of Golgi preparations². While these techniques retain an important role in the mapping of neuronal processes, they are no longer acceptable for the demonstration of intimate neural contacts and their interpretation is questionable. Moreover, the synapse-like contacts the Scheibels described were limited to "the application of axonal boutons en passage and boutons terminaux to the cytoplasm and/or nucleus of the oligodendrocyte". Such limited contacts, if they exist, are not highly relevant to a general theory of impulse transmission. More relevant are certain observations by electron microscopists. When adjacent cells come together the outer limits of their osmophilic plasma membranes usually remain separated by an interval of 100–150 Å. In certain situations this interval closes with fusion between the surface dark layers of the adjoining cells. Closed contacts in the central nervous system are formed between glia cells and processes and between endothelial cells³ but have not been observed between neurones and neuroglia. Furthermore, astrocytic processes are arranged in such a way that they isolate the receptive surfaces of

neurones from all axon terminals except those that synapse specifically on them⁴. Since neuroglia-neuronal contacts are open, there exists a perineuronal space of 100–150 Å; this may be contained by closed contacts between glia cells and, as will be seen, is available for diffusion. While neuroglia-neuronal contacts are open and apposed plasma membranes are not thickened, the contacts are not unspecialized. Where certain glial processes abut against neuronal perikarya or dendrites, there is often a sub-surface cistern beneath the neuronal plasma membrane⁵. The sub-surface cistern may have a mitochondrion closely applied to the inner surface⁶. Taken with the presence of an $\text{Na}^+ - \text{K}^+$ stimulated ATPase at the outside of the glia cell membrane⁷ and the observation that cortical neuroglia reacts to an increase in potassium concentration by an increase in oxygen uptake⁸, these observations suggest that certain glia cells may be concerned with the control of the ionic content of the perineuronal intercellular space. Such a control system is necessary to prevent continuous depolarization and spread between neighbouring synaptic areas and along the axonal membrane; the possibility of interference between excitatory and inhibitory synapses here is obvious. Potassium ions are lost to the cell not only during the falling phase of the spike potential during impulse transmission but also during the production of the excitatory post-synaptic potential and particularly during the production of the inhibitory post-synaptic potential⁹. It is suggested that, particularly in the cerebral cortex, excess potassium ions from these sources may be mopped up by active transport into glia cells. It is further suggested that under physiological conditions the potassium ions would be restored to the neurones, perhaps by active transfer via the sub-surface cisterns with an apposed mitochondrion providing the energy to drive the ionic pump. Clearly such a system could be overloaded but, given a low-resistance bypass, short-term overloading is likely to result in a damming up of potassium ions⁹ and diversion at the input stage rather than in overflow at the output stage.

Such a low resistance pathway is provided by the intercellular spaces, which are not, however, restricted to those parts of the central nervous system where potassium-induced stimulation of respiration has been demonstrated. In this context the volume of the extracellular space is an irrelevancy. What matters is not the volume (only 5–7 per cent of the total tissue volume¹⁰) but the arrangement of the intercellular spaces and their effective width. It has been argued that the osmiophilic lines on electron-micrographs do not represent the full thickness of the plasma membrane and that unstained outer layers keep them a uniform distance apart. However, as has been mentioned, the osmiophilic lines can fuse and the bulk of evidence favours the view that the lines represent essentially the full thickness of the membranes¹¹. Diffusion through narrow clefts is not free and a theoretical formula has been used to estimate the restriction they impose¹²:

$$\frac{D'}{D} = \frac{(1 - a/r)^2}{1 + 2.4 a/r}$$

where D'/D is the ratio of restricted to free coefficients of diffusion, a is the radius of the particle and r is the radius of the channel. On this basis, the restriction to potassium ions (hydrated radius 1.25 Å) diffusing through a channel of 125 Å diameter would not be great ($D'/D = 0.92$). However, this formula probably overestimates the restriction since it includes a correction for steric effects at the entrance to the channel which does not apply and presumes a cylindrical channel of radius r instead of a linear slit of half-width r . Manegold has demonstrated experimentally that, on the average, the slit half-width needs to be reduced to 15 times the particle radius if diffusion is to be restricted by 50 per cent¹³. On this basis, again, the restriction to the diffusion of potassium ions through 100–150 Å intercellular spaces should be slight.

More significant than either of these approaches is the demonstration that spaces of these electronmicroscopic dimensions in the central nervous system of the leech provide a rapid and effective pathway for the movement of ions and small molecules¹⁴.

Since this primarily perineuronal pathway has been shown to exist and to be available for diffusion, it is unnecessary to involve the neuroglia as an active intermediary in Leão's spreading depression¹. According to the neuronal-contiguous theory of its transmission, potassium or a special substance which may be glutamic acid is released from depressed neurones to excite nearby neurones¹⁴. One need not look beyond the intercellular space to route this spread or to explain the source of the water and ions which enter the apical dendrites¹⁵. Certainly the advance of spreading depression (2–6 mm/min) is too fast to be accounted for solely by diffusion and too slow for orthodox nervous conduction alone, but this is no argument against a combination of these processes in a neurone-space-neurone sequence of spread. This perhaps operates when the potassium mopping-up mechanism of the neuroglia is overloaded. An important objection to a theory involving neuroglia in the sequence is the limitation of spread from one type of cortex to another. Thus, depression does not spread from neocortex to cingulate mesocortex or to the hippocampus or vice versa¹⁴. In these situations the neurones are discontinuous and spread fails to occur although the neuroglia cells are contiguous.

Finally, the possibility and time-scale of diffusion of potassium ions through intercellular spaces militates against the suggestion¹ "that the early stages of memory should be related to changes in ionic distribution". Although the long-lasting type of memory trace seems to be characterized by RNA synthesis, with changes in the base composition, in neurones¹⁶ and neuroglia¹⁷, the early stages, which occur within a few hours of training, may be unaffected by RNA inhibitors¹⁸. Some intermediary process of longer duration must follow the short-term ion changes. Perhaps this includes the induction of ion-stimulated enzymes in response to overloading of a potassium mopping-up and restoration mechanism centred on the neuroglia.

I AGREE with Drs. Wendell-Smith and Blunt that three pre-requisites of the suggested neuronal-neuroglial-neuronal impulse transmission system are: (1) an appropriate topographical relationship between nerve cells and neuroglia; (2) a high capacity for ion transport in glia cells; (3) no significant intercellular diffusion. Since

Wendell-Smith and Blunt regard my supporting evidence for the second of these premises as good, only the two others will be discussed here.

As regards the topographical relationships, no direct synaptic connexion between nerve cells and glia cells is envisaged in the postulated impulse transfer system. The reference to Scheibel and Scheibel's findings was made to emphasize that the idea of a co-operation between neurones and neuroglia in brain function is not a new one, but it was clearly stated that "participation of neuroglia in the transfer of impulses does not . . . necessarily require any direct synaptic contact between nerve cells and glia cells". The mechanism suggested by me represents another, totally independent, way of transferring impulses between the two cell types; a direct synaptic contact is meaningless in this system and the evidence against the findings by the Scheibels accordingly irrelevant in this context.

In the initial phase of the suggested potassium-mediated transfer of impulses "potassium ions lost from a neurone during excitation are transported actively from outside it into glia cells". This is consistent with the widely accepted presence of narrow (100–150 Å) intercellular channels surrounding the cells, and it is important that the volume available for diffusion is small and the routes of diffusion long and complex. The release of potassium ions may therefore cause a temporary increase in the local concentration of potassium, which in turn stimulates the active transport of potassium ions into glia cells.

Admittedly, some diffusion may occur along the intercellular clefts. The extent of this diffusion in mammalian brain cannot possibly be estimated from measurements on the leech central nervous system, which histologically differs grossly from the vertebrate brain^{1,2}; and the findings by Nicholls and Kuffler³ that, for example, sodium ions do not diffuse into certain types of leech glia cells cannot be universally valid, since the sodium space of brain is much larger than the true extracellular space⁴. It is furthermore of no importance that some potassium ions may become passively distributed in the extracellular space—if only the potassium concentration here does not increase so much that a general excitation of nerve cells occurs. What matters is, whether the active transport is large enough to secure that a sufficient fraction of the released ions are transported via predetermined, regulated pathways to exert a selective action on certain nerve cells. To which degree this requirement is fulfilled cannot be estimated by regarding only the possibilities for diffusion but requires knowledge of the efficiency and rate of active transport. No such information is available. It seems, however, thought-provoking that the extracellular fluid in brain cortex is restricted to narrow clefts, and that the extracellular space is small. In this way the active, regulated transport is probably given a possibility to compete effectively with free diffusion. Wendell-Smith and Blunt seem to agree on this point of view, since they suggest that "excess potassium ions may be mopped up by active transport into glia cells".

The fate of the 'mopped-up' potassium ions will depend on the anatomical inter-relationship between adjacent glia cells and thus the possibilities of active transport from one cell directly into another as well as from the 'terminal' glia cell to the perineuronal cleft. The fusion between surface layers of adjoining glia cells referred to by Wendell-Smith and Blunt may constitute the anatomical basis for such a transport.

The hypothesis of a potassium transport through glia cells was primarily provoked by the biochemical, topographical, developmental, and pharmacological analogies between the potassium-induced stimulation of oxygen uptake and spreading depression. It is a result of an effort to combine neurochemical, neuroanatomical and neurophysiological evidence and experimentally less well founded than the initial uptake of potassium ions by glia cells.

I admit it is "unnecessary to involve the neuroglia as an active intermediary in Leão's spreading depression", but the concept that neurones behave like pools of potassium ions which are released by potassium and in turn transported actively by glia cells to propagate the response fits with the evidence mentioned and gives a simple explanation of the rate of the spread. The massive, self-propagating character of the response is probably due to the initial excitation of a very large number of neurones. The subsequent release of potassium ions must accordingly also be large, and they are transported in all directions; the absence of either cell type must, of course, inhibit the propagation. By the term 'overloading' is understood that the potassium release is "so intense that a certain time is required for its uptake in neuroglia"; this is the reason that neurophysiologically a depression is observed instead of an activation and consistent with the concept by Wendell-Smith and Blunt: "overloading is likely to result in a damming up and diversion at the input stage". Altogether, I therefore find that their concepts differ only slightly from mine, and this may perhaps be taken as an indication that the proposed mechanism is at no variance with present neuroanatomical thinking.

ENTOMOLOGY

An Improved Method for obtaining, *in vitro*, Uniform Cell Monolayer Sheets from Tissues of the Tick, *Hyalomma dromedarii* (Ixodidae)

THE first report on the cultivation of tick (Ixodidae) tissues *in vitro* was that of Řeháček¹ in Czechoslovakia, who obtained proliferation of fibroblast type cells in explants from developing adults of *Dermacentor marginatus*. Řeháček^{2,3} afterwards improved his techniques and was able to obtain cell monolayers by trypsinizing tissues of developing adults of *D. marginatus*, *D. pictus* and *Hyalomma dromedarii* and growing them in test-tubes and Carrol flasks. His methods for preparing tick tissues and of culturing them are fully described elsewhere⁴.

In culturing tissues from developing adults of *H. dromedarii*, we found that certain modifications in Řeháček's methods and of his medium produced better results. There was improved dissociation of the tissues and hence a higher cell yield when the tissues were agitated by a magnetic stirrer in 0.25 per cent trypsin which had been prewarmed in a 37° C water bath. The resulting cell suspension was filtered through sterile gauze to remove large pieces of undissociated tissue.

The pH of the medium was adjusted to 6.9, 0.2–0.4 higher than in Řeháček's experiments, and this appeared to produce more rapid attachment of the cells to the glass. At 27°–29° C, adherence of cells to the glass surface started in less than 20 min and, by 18–20 h, cell attachment was nearly complete. In our earlier trials, we used Leighton tubes with and without cover-glasses and incubated them horizontal. In these tubes, there was a tendency for the cells, over the major part of the glass surface, to aggregate in clumps from which fibroblast type cells grew out, but they never formed a continuous sheet. Although towards the bottom part of the tubes there was a narrow strip where the growing cells had formed a more or less continuous sheet, growth of the culture as a whole was by no means as satisfactory as the uniform cell monolayers obtained in vertebrate cell cultures. Mitoses in the Leighton tube cultures were seen up to 10 days, the same period as in Řeháček's cultures⁴.

Fig. 1. Cultivation of tick cells in test-tubes, without cover-glass (A) and with raised cover-glass (B)

In subsequent investigations to improve the cultures, we used 'Pyrex' glass test-tubes 125 mm x 16 mm, incubated at an angle of about 7°, and found that, as in the Leighton tubes, by about the 4th day, there was a patch of cells growing into a sheet towards the bottom of the tubes, but over the rest of the glass surface the cells formed scattered aggregates (Fig. 2, B, D). We next introduced into the test-tubes, before seeding of cells, rectangular cover-glasses (40 mm x 11 mm) primarily with the object of obtaining growing cells on the cover-glasses for microscopical examination. However, the width of the cover-glass was such that it remained raised above the curved side of the tube (Fig. 1, B) with the cell suspension underneath it. In such tubes the cells always grew out on the glass surface of the tube as an excellent, uniform monolayer sheet, consisting mostly of epithelial type cells. There were no cells, or only a few, attached to the cover-glass. In appearance, these cell sheets (Fig. 2, A, C) were similar to those obtained from vertebrate cells. Furthermore, the metabolism in the tubes appeared to be higher with cover-glasses than without as evident from the more rapid change in the pH of the covered medium. The cell sheets in the tubes with cover-glasses have, with periodic changes of medium, been kept for up to 35 days without any obvious signs of degeneration. There was recurring mitotic activity and mitoses were common even 30 days after seeding, the longest period recorded so far for tick tissues *in vitro*.

What caused and maintained the better growth in the tubes with cover-glasses in these preliminary investigations is not clear. Cell aggregation which occurred by about the 4th day in tubes without cover-glasses would appear to slow down metabolism. One explanation may be that the partially closed system of the cell suspension

in medium trapped between the overlying cover-glass and the curvature of the tube produces physical forces which prevent the cells from aggregating. Towards the free surfaces of the medium, that is, at the end and less so at the edges of the cover-glass where these forces may be less, the cells do tend to form clumps, particularly at the open end (Fig. 2, A, C). It is also possible that this confined system produces, except towards the limits, partially anaerobic conditions which may be more suitable for the continued growth of the cells, or that the carbon dioxide evolved during the metabolic processes is prevented from diffusing out to any great extent, thus increasing the carbon dioxide tension of the medium. These aspects are now under investigation. But, whatever the explanation may prove to be, inclusion of an overlying cover-glass appears to maintain consistently better cell growth and a more uniform cell monolayer sheet than if it is omitted. This modification of technique may also enhance the utility of the cell cultures for the cultivation of viruses and other pathogenic organisms, the purpose for which the technique is primarily intended.

We thank Dr. J. Řeháček of the Institute of Virology, Bratislava, Czechoslovakia, for his help at the beginning of these experiments, also Prof. D. S. Bertram, director of this Department, and Prof. Forrest Fulton of the Department of Bacteriology and Immunology for their advice, Mr. D. F. King for staining the tubes, Mr. C. J. Webb for taking the photograph and Miss Anne Caisley for preparing Fig. 1.

MICROBIOLOGY

Occurrence of Dimorphic Forms of *Mycobacterium phlei*

DURING the course of an investigation concerning the lipid fractions of *Mycobacterium phlei* it was found that liquid cultures which had been incubated for a period of 1 week at 37° showed the formation of a dry, rough pellicle. However, after incubation for 5 weeks only a sparse pellicle remained and the rough pellicle observed at 1 and 2 weeks had fallen to the bottom of the pan, forming a thick, mucoid deposit. This deposit was unlike the granular deposit obtained in young cultures of mycobacteria and it was therefore decided to investigate the morphology of the organisms in these cultures. Using the method described in this communication, three morphological phases of growth from *M. phlei* were consistently obtained, which formed part of a definite cycle of growth.

Non-acid-fast stages in the life-cycle of different members of the Actinomycetaceae and Mycobacteriaceae have frequently been observed¹. Rich² noted that considerable differences in the morphology of individual organisms could be found and this depended on the age of the culture, the character of the medium and the conditions of growth. Csillag³ has obtained various non-acid-fast organisms from *Mycobacterium tuberculosis* var. *hominis* and atypical mycobacteria. The typical acid-fast bacilli were termed 'Form I' mycobacteria and five different non-acid-fast types of organ-

Fig. 2. A, B, Culture 7 days after seeding, stained with Mallory's stain; A, with raised cover-glass; B, without cover-glass. C, D, Culture 10 days after seeding, stained with haematoxylin and eosin; C, with raised cover-glass; D, without cover-glass

ism were grouped together under the heading 'Form 2' mycobacteria. Csillag⁴ found that a coccoid form could be obtained from the 'Form 2' mycobacteria and regarded these as conforming with the definition of mycococci, which were originally described by Krassilnikov⁵. The genus *Mycococcus* is defined in *Bergey's Manual*⁶ as consisting of cells of variable size and shape, generally spherical, occurring singly, in short chains or in clumps. Multiplication is by fission, constriction or bud formation. The cells are non-acid-fast, Gram-positive, aerobic and grow well on ordinary culture media.

The media used were: (a) 1 per cent glucose meat extract broth; (b) meat extract agar; this was prepared by mixing 1 lb. fat-free minced horse heart, 10 g peptone, 5 g sodium chloride and 1 l. tap-water, and heating for 30 min at 65°. The following day the mixture was heated for 2 h at 100°, filtered through coarse paper and the pH adjusted to 8.5. The broth was steamed for 45 min and the phosphate deposits filtered off on fine filter paper. Difco agar (14 g) was added and the mixture steamed for 30 min, filtered and sterilized at 15 lb. for 20 min; (c) a modified Sauton medium^{7,8}: 5 lb. potatoes were left overnight in 4 per cent KMnO_4 solution, washed in distilled water, peeled and chipped. Distilled water (5 l.) and glycerine (1 l.) were added to the chipped potatoes and the mixture was left to infuse at 60° overnight. The potato extract was filtered off through gauze. The following ingredients were added to the extract: 48 g sodium glutamate, 3 g K_2HPO_4 , 0.3 g brown ammonium iron citrate, 12 g citric acid, 3 g magnesium sulphate. The total volume was adjusted to 12 l. and the medium was steamed for 30 min. After filtering off any deposits the medium was distributed in 500-ml. amounts in 2-l. Caroll flasks (J. Jobling and Co., Ltd.) and autoclaved at 10 lb. for 10 min.

Cultivation of the organisms was as follows: A starter culture was prepared by inoculating a flask of 1 per cent glucose broth with *M. phlei* and this was incubated for 3–4 days at 37°. Part of the pellicle from this starter culture was transferred on a large loop to the surface of the Sauton medium. The cultures were incubated for six weeks at 37°.

Smears of the deposit in the Caroll flask were stained by the method of Gram and the Ziehl Neelsen method⁹. Examination of the stained preparations showed that 25 per cent of the cells were acid-fast and the remaining 75 per cent were non-acid-fast (Fig. 1), and these showed two different morphological types. The first of these was a Gram-positive rod with square ends; the rods sometimes appeared curved or bent double. The second type was a poorly stained Gram-negative organism containing a large clear ovoid inclusion.

Meat extract agar plates, previously incubated for 48 h to check sterility, were inoculated with the deposit from the 6-week-old cultures and incubated at 37°.

Fig. 1. Cellular morphology of a six-week-old culture of *M. phlei* ($\times c. 750$)

Fig. 2. Gram stain of Phase 1 of *M. phlei* ($\times c. 750$)

Fig. 3. Sudan black stain of Phase 1 of *M. phlei* ($\times c. 750$)

After 36 h large flat colonies of acid-fast *M. phlei* were present; but after longer incubation small regular colonies, 0.4–0.6 mm in diameter, and larger irregular colonies, 2–3 mm in diameter, were found. From both types of colony sub-cultures were grown on meat extract agar. However, it was found that when these organisms had been sub-cultured several times the morphology, which had been checked at each stage, was obviously changing. Consequently, a further set of meat extract agar plates was inoculated with the rod-form, incubated for three days at 37° and then left at room temperature for one month. It was found that the colonies on these plates, which were 3–6 mm in diameter, contained coccoid forms of variable size, arranged singly, in pairs or in clusters.

The morphology and staining reactions of the organisms isolated may be summarized as follows:

Phase 1. Large, non-acid-fast, motile, Gram-variable rods with a thick cell wall and a thin capsule. Each cell contained two or more large inclusions which were quite distinct and stained positively with Sudan black⁹ (Figs. 2 and 3).

Phase 2. Small, Gram-negative, motile, pleomorphic organisms containing a large inclusion which almost filled the cell. These inclusions were sometimes acid-fast but only gave a very weak spore-stain reaction. After delipidation of the smear with alcohol-ether (1:1) for 2 min these ovoid inclusions were strongly stained by a spore-stain method⁹. It is possible that these reactions may be related to the acid-fastness (Figs. 4 and 5).

Phase 3. Gram-positive, capsulated, non-motile cocci of variable size, lying singly, in short chains or small clusters. These organisms contained no large inclusions and were non-flagellated (Fig. 6).

These phases 1 and 2 of growth from *M. phlei* are identical to two phases of growth included under the term 'Form 2' mycobacteria by Csillag⁴. Phase 3 from *M. phlei*

Fig. 4. Spore stain of Phase 2 of *M. phlei* after delipidation of the smear ($\times c. 750$)

Fig. 5. Gram stain of Phase 2 of *M. phlei* showing the unstained ovoid inclusions ($\times c. 750$)

Fig. 6. Gram stain of Phase 3 of *M. phlei* ($\times c. 750$)

corresponds to the 'mycocoecal stage' isolated by Csillag⁴. Since it is possible to obtain the same phases of growth, the method described here has some advantages over previously reported procedures. The phases 1, 2 and 3 from *M. phlei* were obtained within 7 weeks without aeration of the cultures, whereas the 'Form 2' and 'mycocoecal' stages were obtained after 14–52 weeks incubation with intermittent aeration^{3,4}.

The existence of a growth-cycle in mycobacteria has been suggested by various workers¹⁰ although the precise nature of this cycle has never been determined. McClung¹¹ has described the cyclic nature of growth and the morphological changes which occur in the different species of the genus *Nocardia*. It is well known that a close relationship exists between the two genera *Nocardia* and *Mycobacterium*^{12,13}. Consequently, if such a growth-cycle could be found in all species of mycobacteria there would be additional evidence to suggest that *Nocardia* and *Mycobacterium* should be included in the same family.

Further biochemical and serological experiments are being carried out with these phases of growth isolated from *M. phlei* in order to determine the nature of this growth cycle.

I thank Miss Kate McLean for her technical assistance in this work.

VIROLOGY

Propagation and Properties of Hepatitis Virus

TESTING a newly developed chemical reaction, we found the virus of hepatitis to consist of pure deoxyribonucleic acid without proteins, contrary to other known forms. This was investigated and confirmed as follows: by treatment with alcohol the virus can be precipitated like the nucleic acids and can be dissolved afterwards without loss of activity. With other virus such treatment led to total inactivation^{1,2}. This property of the hepatitis virus enables one to prepare highly concentrated and pure samples, which do not contain proteins from tissues or other virus.

The hepatitis virus itself cannot permeate into the cell, the protein hull of virus being, as is well known, responsible for the affinity to the host cells. However, if the virus is brought into the cell by special treatment, then propagation and formation of plaques occur as with other viruses. The fact that, in such cases, the virus can be propagated in many tissue cultures confirms its character as a pure nucleic acid³.

Enzymes that cleave nucleic acids degrade the virus, but trypsin, papain, Na-deoxycholate and ether are without any effect.

In vitro, the virus can be fixed by actinomycin like other deoxyribonucleic acids.

The following factors also indicate that the nucleic acid of the hepatitis virus is deoxyribonucleic acid (DNA): (1) Total inactivation by ENase, but not RNase; (2) 5-iodo-2'-deoxyuridine yielding an inhibition of propagation *in vivo*, while substances influencing the metabolism of RNA, such as 8-azaguanine, 2-thiouracil and 5-fluorouracil, have no influence; (3) actinomycin inactivates the virus *in vivo* as well as *in vitro*; it is known that actinomycin blocks DNA, but not RNA, *in vitro*; (4) estimation by the method of Schmidt and Thannhauser⁵ confirms the DNA character of the virus.

The hepatitis virus can be propagated on the chicken embryo by the following technique: (1) Treating the chorio-allantoic membrane with hyaluronidase just before inoculation; this loosens the tissue and thereafter the virus can passively permeate into the tissue; (2) the

cytotoxic effect, especially from sera, can be removed by dilution, otherwise it prohibits multiplication of the virus; (3) the effect of DNA in cleaving enzymes such as DNase I and DNase of tissue origin will be greatly reduced by adding 0.01 moles Na-citrate and shifting the pH up to 8.5.

In tissue cultures the cells were washed before inoculation with 1 M NaCl, pH 8.2. The inoculation fluid contained hyaluronidase. Further propagation for many passages in tissue cultures is possible only if the pH of the medium does not go below 7, since pH 6.5 strongly decreases the active virus particles. The optimum pH for preservation of the hepatitis virus is between 8.5 and 9.5.

Plaque formation on the chorio-allantoic membrane appeared on the third day, and in liver and spleen on the fourth day after inoculation, the foci being similar to those of other virus, both morphologically and histologically⁶. In tissue cultures the beginning of the cytopathogenic effect was seen on days 3-4 after inoculation.

Fig. 1. Human hepatitis virus stained with uranyl acetate ($\times 100,000$)

Electron microscopy shows the virus to have a polyhedral shape (Fig. 1). Negative staining with 1 per cent uranyl acetate makes it possible to measure the diameter, which is between 40 and 150 m μ . To determine whether the smaller particles are parts of larger ones, or are the virus itself, we separated the particles by ultracentrifugation. These were then tested for infectivity and diameters measured. The results showed that the smallest particles represent the virus itself.

The virus was propagated from 144 cases of acute and chronic hepatitis epidemica, from serum hepatitis and from a series of normal blood donors. The virus was found in sewage as well as in blood and in faeces. All 144 virus stems tested were identical in electron micrographs and by immunological tests.

For preparation of immune serum from rabbits, the injection of the pure virus suspension with Freund's adjuvant is recommended together with simultaneous application of anabolic steroids. With immune sera prepared in this way 144 stems were tested by neutralization and haemagglutination with erythrocytes of guinea-pig, and a complement fixation test. As has been stated, they all gave the same reaction.

Neutralizing and haemagglutination-inhibiting antibodies were found in patients after complete healing, while complement-fixing antibody was present as well as the virus only in chronically active cases. An efficient disinfectant is 'Havisol' (Schulke and Mayr G.m.b.H., Hamburg), based on phenol. The 6 per cent solution inactivates massive, protein-poor virus suspensions in 2 min. With more proteins present the virus was inactivated by 'Havisol' and 'Parmetol' in 2 per cent solution after 15 min.

As expected, the virus was much more resistant to heat than other viruses, and heating to 75° C for 1 h had no effect at all. Heating above 170° C was necessary to inactivate pure virus suspension with 10 p.f.u., within 1 h. The same suspension was inactivated in the autoclave after 30 min at 2 atmospheres at 134° C. With protein and cations, present heating for 1 h at 195° C, or at two atmospheres, was required to kill the virus. The addition of 2 per cent sodium carbonate led to the total loss of activity within 20 min at 100° C.

The hepatitis virus was more resistant to ultra-violet radiation. Irradiation of 0.5 ml. solutions in Petri dishes at a distance of 10 cm, using a mercury vapour lamp giving 2540 Å emission, produced an area of inactivation of 8.5 cm diameter after 6 min.

Since it was not possible to inoculate man with the virus, we performed the classical experiment of Neefe *et al.*⁷ on human volunteers, as with the propagated virus in chicken embryo. The results were exactly as described by these authors.

'Ring-forms' of Reovirus Particles

SEVERAL investigations utilizing electron microscopy have shown that during reovirus synthesis, progeny virus consisted of particles containing nucleic acid surrounded by protein coats (capsids), and others which were devoid of a central core¹⁻⁴. Negative staining techniques⁵ have afforded a means of following the course of events in infected cells.

The L-48 line of mouse fibroblasts was received from Dr. C. P. Stanners⁶ and maintained in this laboratory in monolayer bottles in Eagle's medium with twice the usual concentration of amino-acids and 10 per cent calf serum. Cells were transferred every third day.

A type 2 strain of reovirus (988) (ref. 7) was prepared and concentrated according to methods previously described⁸.

Sixteen-ounce monolayers of L-48 cells containing 1×10^7 cells were changed with 50 c.c. of pre-warmed medium (35° C) containing Eagle's as before, and 5 per cent foetal bovine serum which had been tested and found to be free of reovirus haemagglutinating inhibiting antibodies⁷. Each 10-oz. bottle was infected with 1×10^6 haemagglutinating units⁹ of reovirus 988 in a 1-ml. volume. This ensured a multiplicity of virus to cell of 100-300 (ref. 10) allowing every cell in the culture to be infected at the time of virus inoculation.

The cultures were then incubated at 35° C for 1, 4, 12, 16, and 36 h. At each of these times supernatant medium was poured away, and the cells washed 10 times with 100 ml. of Earle's balanced salt solution (4° C). The remaining cells were then scraped from the glass with a rubber policeman, and allowed to swell in 3 ml. of a hypotonic medium (10^{-2} M tris, 10^{-3} KCl, 10^{-3} MgCl₂, pH 7.4) for 15 min (4° C). Cell membranes were then disrupted by 10 gentle strokes in a glass Tenbroeck homogenizer (4° C).

These lysates of virus-infected cells were examined on thinly spread films by electron microscopy. Crystalline bovine serum albumen was added to a final concentration of 0.286 mg/ml. to facilitate spreading. Five per cent phosphotungstic acid (PTA) neutralized (pH 7.0) with 1 M KOH was coated with a light film of talcum. One drop of cell lysate was then spread on to the surface. The films remained on the surface of the PTA solution for 5 min. They were lifted on to 'Formvar'-coated grids, and dried on filter paper. The grids were examined in an RCA EMU 3E electron microscope. Observations were made at initial magnifications of 5,000-18,000 diameters.

Virus particles were seen in preparations from infected cells as early as 1 h and as late as 36 h after infection. Complete virus was 69 m μ in diameter and contained a dense core of nucleic acid measuring 48 m μ . Enucleate

Fig. 1. Complete virus, enucleate capsids and a third type of particle, 'ring forms', are seen 12 h after infection. Complete virus and enucleate capsids are 69 m μ in diameter. The 'ring forms' (arrows) are enucleate and 48 m μ in diameter. (\times c. 55,380)

Fig. 2. A group of nucleic acid cores in a preparation made 4 h after infection. (\times c. 35,840)

Fig. 3. Free virus, cytoplasmic vesicles and canaliculi are seen in a preparation 16 h after infection. Capsomeres of the protein coat are discernible. There are enucleate particles and whole virus. (\times c. 35,800)

Fig. 4. Sixteen h after infection, clusters of virus enclosed by a limiting membrane or sac are seen (lower right). (\times 61,800)

particles with a protein coat of capsomeres (capsid) but without central cores were present in all preparations.

At 12 h or more following infection of *L*-cells by reovirus, several changes in virus progeny were observed. In addition to complete and coreless forms, a third type of particle was noted in some fields. These were empty particles with an outer limiting membrane. Capsomeres were not seen (Fig. 1). These 'ring forms' had a diameter of 48 m μ , equal to that of the central core of the complete particle. A fourth type of virus material of similar dimension was also observed. These were solid electron-dense polygonal particles (Fig. 2) which appear to be the nucleic acid or core material.

At 16 h after infection aggregations of virus particles enclosed within a limiting membrane or sac were seen (Figs. 3 and 4). Several points concerning reovirus became evident. The appearance of ring forms at 12 h after infection suggests new virus synthesis. The ring could well be protein. This suggests that reovirus protein consists of 2 morphological types, capsomere and 'ring'. The inner layer of the ring was noted by Vasquez and Tournier². It had never been observed free of capsomere protein, and the time of appearance was not described. 'Ring forms', which have a diameter equal to that of the nucleic acid core, could serve as an outer covering of the nucleic acid or as an inner lining for capsomeres.

The observation of virus aggregates in a sac is reminiscent of an earlier observation by Horne and Nagington for poliovirus¹¹. Such a cytoplasmic structure has recently been shown to be involved in the synthesis and assembly of poliovirus components¹².

GENETICS

'Complement Fractionation' in a Natural Hybrid between *Rubus procerus* Muell. and *R. laciniatus* Willd.

Rubus procerus Muell. and *R. laciniatus* Willd. occur sympatrically over a wide range of area in the coastal Pacific north-west of the United States. Natural hybridization between these two pseudogamous apomictic species has been shown to take place by Bammi and Olmo¹. One such partially sterile natural hybrid (6412A), collected from Riverton, Oregon, proved very interesting cytologically. The present report deals with the peculiar cytological behaviour of this hybrid clone.

The chromosome analyses in this study were made from temporary squash preparations according to the alcoholic-carminic technique described by Snow².

All clones of *R. procerus*, *R. laciniatus* and the hybrid clone were tetraploids with 28 chromosomes in their somatic cells. Stages prior to diakinesis or metaphase I were not suitable for analyses.

Both *R. procerus* and *R. laciniatus* behave as segmental allopolyploids. Usually not more than 1-2 quadrivalents are formed at microsporogenesis. The hybrid clone (6412A) showed a peculiar kind of abnormality. In about 60 per cent of the microsporocytes two chromosomal plates were present, instead of the expected one, at metaphase I. These two plates behaved as independent units during the rest of the meiosis. Various other abnormalities like non-disjunction, lagging of certain chromosomes at first and second division of meiosis, separate or in conjunction with the above described abnormality, were also observed. About 1.5 per cent of the microsporocytes in *R. laciniatus* also showed more than one group of chromosome at metaphase I. The net result of the phenomenon of multiple plates at metaphase I and the behaviour of these groups of chromosomes to operate independently of each other in subsequent stages results in the production of an excess of sporads at telophase II. Table 1 shows that at telophase II, this plant had only 29-30 per cent of the cells with four sporads. This is in contrast to the clones of the parents and the hybrids, where cells with four sporads were about 97-99 per cent of the total. Almost all the rest of the cells had excess sporads.

Table 1. FREQUENCY DISTRIBUTION OF CELLS AT TELOPHASE II WITH REGARD TO NUMBER OF SPORADS PER CELL IN THE SUSPECTED HYBRID CLONE 6412A

Total cells studied	Cells with sporads numbering												
	4+	1	2	3	4	5	6	7	8	9+			
273	Micronuclei No.	18	1	3	8	4	80	42	65	12	42	9+	2
	Per-centage	6.59	0.37	1.10	2.93	29.30	15.38	23.81	4.40	15.38	0.74		

Thompson³ introduced the term 'complement fractionation' for the general phenomenon wherein "the chromosome complement is sub-divided into independently operating groups within a cell". Thompson³, in working with the cultivated variety 'Boysen' of the genus *Rubus*, found a similar situation of sub-division of the chromosome complement into independently operating groups within meiotic cells. In her interpretation there were no definite implications as to the genetic constitution of the end-product. However, the present study goes a step further in proposing that the two sub-groups of chromosomes at metaphase I in fact belong to different genomes, namely *R. procerus* and *R. laciniatus*. This interpretation is based on the following observations.

(1) Sub-division does not seem to be a completely random process. The number of bivalents in each group at metaphase I tends to be 7 (14 being the gametic number for both *R. procerus* and *R. laciniatus*).

(2) Rarely, more than 2 sub-groups were observed at metaphase I.

(3) Each sub-group seems to have a separate spindle. This is supported by the following observations:

(a) Lack of synchronization of 2 groups in some cells, and
(b) their separation in different planes in a 3-dimensional cell.

(4) Counts made at anaphase II show that chromosomes number in each group tends to be 7.

Since the frequency of this phenomenon is different in different clones, it is assumed to be genotypically controlled.

No definite conclusion as to the time or method of origin can be drawn from this work. Some indication of sub-grouping of chromosomes in somatic cells was also seen. It is probable that actual separation of genomes had taken place in the premeiotic cells.

The presence of 'complement fractionation' in the cells of an organism has many implications. It may be an indication of its obvious or concealed hybridity. It is quite conceivable that one of the resulting gametes may be functional and may take part in fertilization. This could result in the formation of unique segregants which would be expected to be rare or impossible in the normal reproductive pattern. As pointed out by Thompson³, the separation of single genomes which form functional gametes can have value in the discovery of ancestral species of polyploids. There, of course, then exists the fascinating possibility that the genome of an ancient diploid trapped inside the constitution of a polyploid (in this case, an apomictic one) might also be released. This phenomenon might also provide a method by which the polyploid level of a species may go down.

Examples of 'complement fractionation' have so far been reported in cultivated plants of hybrid origin, for example by Thompson³ and in tomato by Gottschalk⁴, and in *Rubus* by Hull and Britton⁵, that were previously subjected to colchicine treatment. This is probably the first instance where a naturally occurring plant shows this phenomenon.

I thank Prof. H. P. Olmo for advice.

SOIL SCIENCE

Thermistor Hygrometer for determining the Free Energy of Moisture in Unsaturated Soils

IN any investigation involving the movement of moisture through soils, the measurement of the free energy or total potential of the soil moisture still remains one of the chief problems. The basic requirement of any satisfactory technique for such measurement is that it should depend on some property which is uniquely related to the free energy of the soil moisture and is in no way affected by the soil type. One such property is the relative vapour pressure or humidity in equilibrium with the soil moisture as given by equation (1).

$$h = \frac{RT}{Mg} \log_e \frac{p}{p_0} \quad (1)$$

where h = free energy (cm water); R = universal gas constant; T = abs. temp.; M = molecular wt. of water;

$g = 981 \text{ cm/sec}^2$; $\frac{p}{p_0}$ = relative humidity.

Fig. 1. Comparison of theoretical (solid lines) and measured curves (broken lines)

Fig. 2. Probe P; time to reach 0.3 mV for 16-h reading

The amount of capillary condensation in a porous medium from some fixed initial condition is closely related to the ambient humidity. The porous medium chosen for study was the micro-porous glass coating on a thermistor bead. It has been shown^{1,2} that glass surfaces may have effective surface areas many hundred times greater than the nominal area of the surface. The initial condition was established by heating the thermistors with their normal operating current in the room atmosphere at approximately 60 per cent humidity for 1 h. The capillary moisture which afterwards condensed on the glass surface could then be measured by the heat energy required to vaporize this moisture or more simply the time delay in the temperature rise as current was passed through the thermistor.

The original experimental work was carried out using a two-thermistor probe sealed into a sample tube. One thermistor, enclosed in an air-tight compartment brought to approximately 0 per cent humidity with silica gel, was used as the standard in a Wheatstone bridge circuit with a 1.35-V d.c. supply from a mercury cell, while the second thermistor was open to the sample atmosphere. The thermistors were 'zeroed' to their 'final' condition by

passing the current for 1 h. After allowing a period of 16 h for capillary condensation to take place, the current was again switched on. Typical readings are shown in Fig. 1 for Stantel 'P23' thermistors and for standard sodium chloride solutions supported on filter paper.

Although the standard thermistor compensated for small changes in mean temperature, differences in temperature between the thermistors and the sample could cause serious errors. These errors were minimized by carrying out the experimental work in a constant temperature room ($\pm 0.1^\circ\text{C}$) with the sample tube and probe placed in an 18-in. cube of polystyrene insulating foam.

Fig. 1 also shows theoretical curves of the temperature difference between a 'F23' thermistor in dry air (that is, the standard) and the second 'P23' thermistor also in dry air, but after time delays corresponding to the experimental curves. These curves were calculated³ assuming the heat is produced in a sphere of perfect conductor surrounded by an infinite region.

In most of the later work, the whole temperature curve was not recorded, and only the time to reach a temperature difference corresponding to a bridge output of 300 μV was measured on a stop-watch. This gave a satisfactory curve between Schofield's pF and the reading in seconds between pF 2.5 and 5.0 as shown in Fig. 2. During the duration of the test, a period of about 2 months, no surface contamination of the porous surface was apparent. Similar curves were also obtained for other types of thermistors and for other capillary condensation times. Times less than 1 h still gave satisfactory calibration curves for more rapid measurements in the range pF 2.5 to 5.0, but with a lower sensitivity.

In the present work a new simple two-thermistor probe is being used with the standard coated with water repellant. Although this work is not complete, similar curves are being obtained to that shown in Fig. 2, using equipment that can be purchased for a few pounds. This technique shows considerable promise in the measurement of free energy of soil moisture in the range pF 2.5–5.0.

Photographic Reproduction of Soil Fabric Patterns

An important prerequisite for a satisfactory fabric analysis of any complex, multi-component fabric pattern is the requirement that the component individuals can be relatively easily recognized as to their nature and their geometrical relationships towards adjacent individuals. In rocks, for example, the various mineral individuals can, under average conditions, be recognized readily and clearly distinguished from adjacent crystal individuals. As a result, rock fabric analysis can usually be carried out directly on the image provided by the microscope.

The microscopical image of soil fabric patterns is, as a rule, very complex. Thus, particularly in spatial distribution analysis¹, the nature of the individuals of the various components may be rather difficult to establish, or boundaries between components may appear hard to locate. For this reason, even elementary soil fabric analysis tends to develop into an extremely slow, tiresome and costly process, particularly if areas larger than the field of the microscope or even whole thin sections are involved.

The obvious solution to this problem is to replace the original microscope image of the pattern by a simplified

Table 1. PHOTOGRAPHIC EFFECTS OF THE VARIOUS STEPS IN THE PROCEDURE

Step No.	Photographic product	Type of light	Appearance of 'primary' fabric elements		
			Skeleton grains	Clay matrix	Pores
Step 1 A B	Negative Positive transparency	Ordinary parallel light Ordinary light, parallel beam or diffuse	Black White	White* Black	Black White
Step 2	Negative	Plane polarized light, rotating crossed Nicols	Black	White	White
Step 3	Combination of positive transparency (1B) and negative (2)	Ordinary parallel light	See step 4	Black	White
Step 4	Negative	Ordinary parallel light under an angle of approx. 70°-80°	White areas surrounded by fine, black lines	White	Black
Step 5	Print or enlargement of negative (4)	Ordinary light, parallel beam or diffuse	Black areas surrounded by fine, white lines	Black	White

* Depending on the colour of the clay material in the thin-section. If sufficiently reddish, the result can be obtained by using the appropriate type of photographic emulsion. If the colour of the clay material is insufficiently reddish, a suitable preferential staining of the clay can be considered.

graphical model which contains all the required information but no unnecessary details. The ideal graphical model therefore should possess the following major properties: it should show all relevant constituents in their true size and shape ratios, and in their mutual spatial relationships; it should also show all the individuals of any one constituent in the same way (for example, skeleton grains in black, clay matrix in grey, pores in white, etc.). Simple drawing or tracing of the microscope image seems attractive, but is, particularly with the usually complex soil fabric patterns, extraordinarily time-consuming and often insufficiently accurate. Ordinary photomicrography, also in polarized light between crossed Nicol prisms, is accurate indeed, but still has the main disadvantage of complexity of the original microscope image, and in addition shows the loss of a number of diagnostic characteristics (for example, extinction angle between crossed Nicol prisms, birefringence, etc.). In many instances these characteristics must be determined later in the original microscope image, leading again to an excessive loss of time.

Over some period of time we have tested several combinations of photomicrographic and drawing techniques. Some of these have been applied for a time, but have been rejected, mainly because they were too time-consuming. We have finally adopted a method which virtually satisfies the two conditions of the ideal model. It is a purely photographic technique which does not demand an excessive amount of time spent on routine work, but rather calls for appreciable photographic experience and skill, as well as for very accurate working methods.

The steps in the actual operation can briefly be described as follows:

1. (A) The area of the soil thin section to be investigated is photographed at the desired magnification and in ordinary transmitted light. (B) From the negative

obtained a positive transparency is made by contact printing.

2. The same area of the thin section is then photographed again without altering the position of camera, microscope or thin section. The exposure is now made, however, in plane polarized light between crossed polarizing filters or Nicol prisms. During exposure the crossed polarizing filters or prisms are simultaneously rotated through an angle of at least 180°. The result of this exposure is a negative, which is directly used in the next step.

3. The positive transparency of step 1B and the negative of step 2 are now put together with the sensitized sides of both film-sheets on the outside and the corresponding parts of the images fitting very accurately. The fitting together of the corresponding parts of the images is the most critical part of the whole procedure, and must be carried out with the utmost care to ensure success of the whole operation. Once the fit of the two film-sheets is perfect, they should be joined semi-permanently or permanently.

4. From the joined set of the positive transparency and the negative, a new negative is now produced in the following manner. The combined two film-sheets, with the third, new film-sheet directly underneath, are exposed to a beam of parallel light (for example, from a photographic enlarger or a microscope lamp) in such a way that the plane of the three film-sheets makes an angle of about 70°-80° with the axis of the light beam. While exposing, the stack of three film-sheets, maintaining the previously mentioned angle of 70°-80°, is rotated through an angle of at least 360° around the axis of the light beam.

5. The new negative produced in step 4 can now be printed or enlarged in the ordinary way.

The final result of the whole operation is demonstrated in Fig. 1, which shows an area of a thin section of an arid red earth from Alice Springs, N.T., Australia. Nearly all skeleton (quartz) grains are shown as black areas surrounded by a fine white line. The very few quartz grains which are shown as white or whitish areas in the figure are those which in the original thin section were cut perpendicular or nearly perpendicular to their optical axis. The majority of these reveal themselves in the photograph immediately by their size and shape. In only very few instances will it be necessary to return to the original thin section for additional information. In the same figure the clay matrix is shown in solid black, and the pores in solid white.

The results and effects of the various steps are described in Table 1.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 8

PLASTICS INSTITUTE, PLASTICS PROPERTIES DISCUSSION CIRCLE (at the Mandeville Hotel, Mandeville Place, London, W.1), at 3 p.m.—Mr. R. A. Horsley: "Creep Properties of Thermoplastics".

SOCIETY OF CHEMICAL INDUSTRY, COLLOID AND SURFACE CHEMISTRY GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. G. P. C. Chambers: "The Colloidal and Surface Properties of Clay Minerals".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Hatfield College of Technology, Hatfield), at 6 p.m.—Discussion on "Is Laboratory Work Really Necessary?" opened by Dr. K. R. Sturley.

INSTITUTION OF MECHANICAL ENGINEERS, NUCLEAR ENERGY GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Fuel Element Behaviour in Gas-Cooled Reactors".

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. A. G. Page: "Some Manufacturing and Processing Techniques in the Electronics Industry".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Lord Rennell of Rodd: "Heinrich Barth and the Opening Up of Central Africa".

Tuesday, November 9

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 1.30 p.m.—Mr. E. F. Schumacher: "Homo Viator and Homo Sapiens".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 2.30 p.m.—Mr. P. R. Barnard and Mr. R. Paul Johnson: "The Ultimate Strength of Composite Beams"; Mr. R. Paul Johnson, Mr. C. H. Finlison and Mr. J. Heyman: "The Plastic Behaviour of Continuous Beams" and "A Plastic Composite Design".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. D. E. Hesmondhalgh: "The Design of the A.C. Servomotor".

INSTITUTION OF THE RUBBER INDUSTRY, LONDON SECTION (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. L. R. Mernagh: "Tyres 1965". 7 p.m.—Dr. A. Schallamach: "Tyre Wear is Complex".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Sir John Baker, O.B.E., F.R.S.: "The Excitement of Engineering Design" (Afternoon lecture for Sixth Form Boys and Girls from Schools in London and the Home Counties. To be repeated on November 10, 16 and 17).

ROYAL INSTITUTION OF NAVAL ARCHITECTS (Joint meeting with the Institute of Marine Engineers, in the Memorial Building, 76 Mark Lane, London, E.C.3), at 5.30 p.m.—Mr. A. F. Willens and Mr. D. R. Murray Smith: "Fire Fighting and Fire Protection in Ships".

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. D. Rogers: "The Portraiture of Molecules" (Inaugural Lecture).*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. Ralph Audy (U.S.A.): "Red Mites and Typhus. III. Emergence of the Typhus Group of Fevers".*

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. A. R. Reece: "Principles of Soil-Vehicle Mechanics".

UNIVERSITY OF LONDON (in the Mechanical Engineering Building, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Prof. W. R. Sears (University of Cornell): "Waves". (Third of four lectures on "Magneto-Fluid Dynamics").*

INSTITUTE OF SCIENCE TECHNOLOGY, LONDON BRANCH (in the Anatomy Lecture Theatre, University College, Gower Street, London, W.C.1), at 6.30 p.m.—Prof. J. Z. Young, F.R.S.: "The Memory in the Brain" (Distinguished Visitors' Address).

Tuesday, November 9—Thursday, November 11

INSTITUTION OF MECHANICAL ENGINEERS, RAILWAY ENGINEERING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1)—Convention on "Interaction Between Vehicle and Track".

Wednesday, November 10

POLAROGRAPHIC SOCIETY (at the National Physical Laboratory, Teddington, Middlesex), at 2.30 p.m.—Meeting on "E.S.R. and Polarography".

SOCIETY FOR ANALYTICAL CHEMISTRY (at the Wellcome Building, Euston Road, London, N.W.1), at 3 p.m.—Meeting on "Automatic Analysis".

ENVIRONMENTAL GROUP (in the Department of Electrical Engineering, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Discussion on "The Adequacy of our Current Measures of the Environment".

INSTITUTE OF METALS (at 17 Belgrave Square, London, S.W.1), at 6 p.m.—Prof. C. S. Barrett (University of Chicago): "X-ray Diffraction at Low Temperatures".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E./I.E.E. MEDICAL ELECTRONICS GROUP (at 9 Bedford Square, London, W.C.1), at 6 p.m.—Dr. D. W. Hill: "Medical Electronics Round the World".

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 6 p.m.—Mr. G. M. E. Williams: "Control in Automatic Mechanical Production".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP—FOOD ENGINEERING PANEL (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Mr. A. Hudson: "Diversification in Packaging".

Wednesday, November 10—Thursday, November 11

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2)—Conference on "Power Applications of Controllable Semiconductor Devices".

Thursday, November 11

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. S. W. Kuffler (Harvard Medical School): "Physiological Properties of Vertebrate and Invertebrate Neuroglial Cells and the Movement of Substances Through the Nervous System" (Ferrier Lecture).

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Access to Airports" introduced by Mr. C. A. Harvey.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. Ralph Audy (U.S.A.): "Red Mites and Typhus. IV. The Impalpable Circus".*

CHEMICAL SOCIETY (in the Chemistry Lecture Theatre, King's College, Strand, London, W.C.2), at 6 p.m.—Dr. B. A. Thrush: "The Formation of Electronically Excited Molecules in Simple Gas Reactions" (Tilden Lecture).

UNIVERSITY OF LONDON (in the Mechanical Engineering Building, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Prof. W. R. Sears (University of Cornell): "Two Weird Boundary Layers". (Last of four lectures on "Magneto-Fluid Dynamics").*

OIL AND COLOUR CHEMISTS' ASSOCIATION (in the Small Physics Lecture Theatre, Imperial College of Science and Technology, London, S.W.7), at 7 p.m.—Mr. F. G. Dunkley: "Airless Spray Painting".

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN AND THE OSLER CLUB (at 17 Bloomsbury Square, London, W.C.1), at 8 p.m.—Dr. F. Guerra and Prof. F. E. Camps: "Phantasica (Drugs, Dreams and Addictions)".

Friday, November 12

ASSOCIATION OF APPLIED BIOLOGISTS (in the Lecture Hall of the British Museum (Natural History), Cromwell Road, London, S.W.7), at 10.50 a.m.—Symposium on "Yield and Quality in Potatoes".

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 11 a.m.—Meeting on "The Flora Europaea Project". Speakers to include Prof. H. Merxmüller (Munich), Prof. D. A. Webb, Prof. D. H. Valentine, Prof. J. Dostál (Czechoslovakia) and Dr. S. M. Walters.

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Dr. S. Callender: "Iron Absorption".*

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. B. M. Weedy and Mr. A. M. Parker: "Method of Predicting the Thermal Loading of an Oil Circuit Breaker".

UNIVERSITY OF LONDON (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Prof. M. J. Langeveld (Utrecht): "Educating a Whole World".*

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. J. R. Napier: "Evolution of the Human Hand".

Saturday, November 13

INSTITUTE OF LINGUISTS (at the British Academy, Burlington Gardens, London, W.1), at 3 p.m.—Mr. Peter F. D. Tennant, C.M.G., O.B.E.: "Language, Communication and Misunderstanding" (Sixth Threlford Memorial Lecture).

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. B. A. L. Cranstone: "The British Museum Expedition to New Guinea".*

Monday, November 15

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 10.30 a.m. and 2.30 p.m.—Colloquium on "Phase Measurement Throughout the Spectrum".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. D. E. Stevenson: "The Assessment of Possible Health Hazards Associated with the Use of Pesticides".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. Ralph Audy (U.S.A.): "Red Mites and Typhus. V. Old and New Horizons".*

INSTITUTION OF MECHANICAL ENGINEERS, MANUFACTURE AND MANAGEMENT GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Engineer and the Law".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. Colin Cherry: "The Nature of Human Communication". (First of three Cantor Lectures on "World Communication").

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at the College of Further Education, Hatfield Road, St. Albans), at 7.30 p.m.—Dr. J. S. Goutlay and Dr. C. K. Warren: "The Chemist's Contribution to the Building Industry of the Future".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

ASSISTANT IN VETERINARY CLINICAL BIOCHEMISTRY—The Secretary of the University Court, The University, Glasgow (November 10).

DEMONSTRATOR/SENIOR DEMONSTRATOR IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Newcastle upon Tyne, 2 (November 12).

LECTURER OR ASSISTANT LECTURER (with considerable field experience of applied geology, preferably on the side of engineering) in GEOLOGY AND MINERALOGY—The Secretary, The University, Aberdeen (November 13).

LECTURER (COMPUTER MANAGER) (graduate with experience of computer systems and administration); and a SENIOR LECTURER (with suitable experience in some aspect of computing science such as system programming) IN THE COMPUTING DEPARTMENT—The Secretary of University Court, The University, Glasgow (November 15).

LECTURERS or ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF PHILOSOPHY—The Registrar, The University, Leeds, 2 (November 15).

PROFESSOR IN MATHEMATICAL STATISTICS AT THE UNIVERSITY OF CAPE TOWN—The Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (November 15).

LECTURER IN CONTROL or DYNAMICS IN THE DEPARTMENT OF ENGINEERING—The Registrar, The University, Leicester (November 17).

SENIOR LECTURER and a LECTURER IN THE NEW LABORATORY OF GENERAL PHYSIOLOGY—The Registrar, The University, Leicester (November 17).

HEAD OF THE DEPARTMENT OF BIOLOGY—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (November 19).

LECTURER or ASSISTANT LECTURER IN MEDICINE—The Registrar, The University, Sheffield (November 20).

LECTURER or ASSISTANT LECTURER (preferably specialized in modern analysis or topology) IN PURE MATHEMATICS—The Registrar, The University Sheffield (November 20).

UNIVERSITY DEMONSTRATOR (with an honours degree and postgraduate teaching and/or research experience) IN AGRICULTURE—The Secretary, School of Agriculture, University of Cambridge, Downing Street, Cambridge (November 20).

LECTURER (preferably with an interest and competence in physiological and animal psychology) IN PSYCHOLOGY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 22).

LECTURER (qualified in chemistry, physics, or a branch of technology, and with industrial or postgraduate experience in a branch of materials science) IN MATERIALS and MOLECULAR SCIENCE—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (November 22).

LECTURER/SENIOR LECTURER IN BIOCHEMISTRY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 26).

TEACHING FELLOWS/DEMONSTRATORS (2) (preferably with an honours degree in rural science, agriculture or science with specialization in plant sciences) IN AGRONOMY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, November 26).

CHAIR OF ZOOLOGY at the University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Kuala Lumpur, November 30).

HEAD (senior research worker, preferably holding veterinary or medical qualifications) OF THE PHYSIOLOGY and BIOCHEMISTRY DEPARTMENT—The Secretary, Houghton Poultry Research Station, Houghton, Huntingdon (November 30).

LECTURER (preferably with a veterinary qualification and interested in chemical pathology) IN THE DEPARTMENT OF PATHOLOGY—The Secretary, The Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (November 30).

PROFESSOR OF PHYSICAL CHEMISTRY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, November 30).

SENIOR LECTURER and a LECTURER IN SOCIAL ANTHROPOLOGY IN THE DEPARTMENT OF AFRICAN STUDIES, University of Natal, Durban—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, November 30).

SUPERVISING GEOLOGIST (with a university degree with geology as a major subject, extensive experience in the examination and assessment of mineral deposits, together with administrative ability) IN THE GEOLOGICAL SURVEY BRANCH OF THE DEPARTMENT OF MINES—The Public Service Commissioner, 184 St George's Terrace, Perth, Western Australia (December 3).

LECTURER or SENIOR LECTURER IN CHEMICAL PATHOLOGY at the University of Otago Medical School, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or the Registrar of the University (New Zealand and London, December 15).

ANIMAL NUTRITIONIST (national of the United Kingdom or the Republic of Ireland, with a degree in agriculture with post-graduate training or experience in biochemistry or agricultural biochemistry) with the East African Agriculture and Forestry Research Organisation, to investigate metabolism of tropical and temperate type cattle with a tropical environment—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. PC213/214/016.

CHAIR OF PHILOSOPHY—The Dean, Faculty of Arts and Science, McGill University, Montreal, Canada.

CHIEF TECHNICIAN (preferably with some knowledge of glassblowing and experience with instrumental analysis, for example, gas chromatography) to take charge of chemical laboratories and stores in the Chemical Engineering Department—The Establishment Officer, University College, Gower Street, London, W.C.1, quoting Ref. Chem. Eng. 15.

LECTURER or ASSISTANT LECTURER (with a degree in physics or general science and/or an ophthalmic optical qualification) IN THE DEPARTMENT OF OPHTHALMIC OPTICS—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

MASTER (preferably graduate in mechanical sciences or engineering) to teach MATHEMATICS and some PHYSICS—The Headmaster, The School, Oundle, Peterborough.

RESEARCH ASSISTANT IN THE DEPARTMENT OF METALLURGY to study the behaviour of point defects in metals using electron microscopy and electrical resistivity techniques—The Registrar, University College of Swansea, Singleton Park, Swansea.

RESEARCH TECHNICIAN (preferably with some experience in growing plants under controlled conditions and of chemical analysis) to assist Prof. J. F. Sutcliffe in an investigation of the absorption and movement of mineral salts in intact plants—The Assistant Registrar (Establishment), University of Sussex, Stanmer House, Brighton, Sussex.

REPORTS and other PUBLICATIONS

UNICAM**SP.800**

spectrophotometer
for routine U.V. analysis
with automation accessories

Save operator time, increase speed and efficiency with Unicam automation for:

ENZYME REACTION RATES

LIQUID COLUMN CHROMATOGRAPHY

**ALL ROUTINE ULTRAVIOLET AND
VISIBLE SPECTROSCOPY**

Please send for descriptive brochure

The brilliant new Unicam SP.800 Spectrophotometer is setting new standards in ultraviolet and visible spectroscopy. The widely acclaimed flat bed presentation, the beam balance smoothing cam and the unique second sample position are among the features which establish it as *the* outstanding U.V. spectrophotometer. Additionally Unicam now offers automation equipment which provides:

AUTOMATIC interchange of up to 4 sample and 4 reference cells

AUTOMATIC re-cycling over any preselected wavelength range

AUTOMATIC recordings at predetermined time intervals

Unicam Precision Spectrophotometers

What do you do with data?

As makers of a range of rugged, reliable, economical and flexible Data and Instrumentation Recording equipment, we know a thousand and one ways of using magnetic recording for data acquisition, storage and analysis—in aeronautics, medicine, industry and university research work. Magnetic recording provides a wide range of band widths and high information packing density. Data expansion and contraction facilities are available which are not possessed by other forms of data acquisition. Thermionic equipment is the lowest priced range of digital and analogue recorders for research—we designed it on the unit principle for complete flexibility of use and we're sure it will answer your data handling problems.

You tell us!

Tell us what your particular research requirements are and we'll show you how THERMIONIC Data Recording Systems can meet them quickly, simply, cheaply. Drop a line to us today.

TRAINING FOR MANAGEMENT IN INDUSTRY

IN one of the most recent of a series of articles on "Research Establishments in Europe" which has been appearing in *Chemistry and Industry*, Dr. Max Stoll, in describing the research laboratories of Firmenich et Cie, Geneva, has a passage on the organization of the laboratories which is highly pertinent to the present discussions on education for management, recruitment and training for the Civil Service and the like. Dr. Stoll observes that throughout his career of forty years with Firmenich the management has always been 'research-minded' and this has ensured the greatest possible efficiency in research. For this his basic principle is to ensure the deepest interest of his research chemists in their work and accordingly they have the utmost freedom.

Dr. Stoll develops his point with the significant comment that three of the directors studied chemistry at the Swiss Federal Institute of Technology, two presenting research theses for a Ph.D. It was not surprising that with a broad-minded and scientifically trained management, Dr. Stoll's rejection of the idea of progress reports met with complete understanding. He is convinced that chemists will write reports spontaneously as soon as they have anything to report, and that insistence on an automatic progress report is a senseless and unnecessary burden. Freed from this, properly selected staff will automatically become interested in the problems of the company, and Dr. Stoll finds that where the choice is wide they tend to choose the most challenging, which he usually encourages them to do, and having made their choice the problem is attacked with much enthusiasm and ingenuity.

The freedom that is thus progressively developing is one thing that makes all the difference between efficient and non-efficient research. Dr. Stoll recognizes, of course, that sometimes this freedom may involve inconvenience: for example, if the company wishes to exploit very rapidly an interesting product which a research chemist has discovered it may be necessary to open the problem to all members of the fundamental research group if the original discoverer does not arrive at an economically advantageous synthesis sufficiently swiftly. Even so, this internal competition can be handled so as to prove a stimulant rather than a frustration.

Here, too, the ultimate responsibility is that of management, which must equally be on the alert to avoid any deterioration in morale such as could, for example, result from continued lack of success in attacking a particularly difficult problem. Publications policy presents its own problems, and Dr. Stoll also suggests that the freedom on which he places such emphasis can minimize these difficulties too as the research worker finds himself a part of the company as well as of his research group. Here again he emphasizes that the corollary is a highly efficient laboratory for developing manufacturing processes.

Dr. Stoll's two main points—the need for a management which has been scientifically trained and which is capable of undertaking the character of scientific work and the essential conditions in which such work is effective, and the provision of the maximum freedom for the investigator—are not always sufficiently to the front even in discussions on the management of research in Britain. Moreover, it should be noted that there is a corollary or implication that is also often overlooked: the freedom he advocates is unlikely to be abused unless the selection of

staff has initially been at fault. This is another responsibility of management which has recently come to the front very much so far as the Scientific Civil Service is concerned, but it is equally important in business and industrial management generally, and was, in fact, one count in an indictment of the training of young people for industry in a forthright report this summer from the Central Committee for Study Groups.

This report maintained that management is too often ignorant of recent advances in education and does not know what qualities are required for different jobs. Generally, the seventeen independent study groups who contributed to the report thought that Britain was suffering from an incalculable loss of potential. While the report itself is concerned more with the training of those entering industry direct from school, advocating replacement of the present apprenticeship system with a single channel of entry into industry for all school-leavers and the termination of set periods of apprenticeship, its conclusions imply management of the same calibre and qualities as Dr. Stoll emphasizes. This amounts, in effect, to something like the managerial revolution which Mr. John Marsh, director of the British Institute of Management, told Section J (Psychology) of the British Association for the Advancement of Science, at its meeting in Cambridge on September 7, had already started in Britain, involving the Government, business, academic institutions and managers themselves.

Mr. Marsh emphasized that our standard of living would depend increasingly on the calibre of management, but considered that the prime responsibility of the Government was to provide the economic conditions which encouraged good management. It was in this context that he asserted that the problem of managerial obsolescence was perhaps the greatest challenge in what he had described as a managerial revolution. In essence, it involved an attitude of mind which it should be the purpose of the business schools and other academic institutions concerned to provide. Mr. D. Pym, who discussed more particularly the identification of effective managerial performance, asserted that at present too many mediocre men were to be found in the highest management of British industry. This would seem to point to indifferent selection as well as to weaknesses in management in an earlier generation, but once again it substantiates in the general field Dr. Stoll's contention in regard to research.

The third paper in this discussion on management training on September 7 came from Mr. W. G. McClelland, the first director of the new Business School which opened in Manchester on September 27. The London school is expected to open next year, and meanwhile the Manchester school has a staff of seven, but it hopes to increase this eventually to about fifty. The opening course, which will last for twelve weeks, is attended by executives between thirty-five and forty from some of the largest companies in Britain, and is intended for those who have shown unusual talents for management. The task of the school is, in fact, seen not as to train managers but to educate them, and Mr. McClelland's paper at Cambridge was concerned with the practicability of this task.

He thought, first, that the tasks of the highest levels of management could be specified broadly enough for this purpose. The manager could, for example, be taught

techniques, such as those of forecasting and the interpretation of accounts, which would help him to make good decisions on courses of action. Through these his understanding of the social, economic and political environment, in which his firm operated and on which his decisions often depend, could be developed. Mr. McClelland agreed that it was very difficult to assess the results of any such training or education, particularly as those selected for courses were probably already earmarked for promotion. Moreover, training which was effective for one man in one situation could be disadvantageous for another in some other situation.

Thirdly, Mr. McClelland, considering the problems of personal development to which this formal education might contribute some solution, emphasized the wider perspectives which specialists taking up senior positions needed. External management courses could enable these needs to be met as well as put technical expertise in a context of wider considerations, and encourage a higher quality of decision. Finally, he insisted that training for business management was essentially an investment, carrying indeed a certain element of risk, as the manager might leave the firm (although this need not be a national loss) but it also offered the probability of a high return.

In so far as poor management may be a contributory factor in the disputes which have led to unofficial strikes and working-to-rule, Mr. McClelland's argument could easily be substantiated. Even more important where good industrial relations are concerned, efficient management could promote the mutual confidence and good understanding which could help the Trade Unions to get on with the long-overdue overhaul and reform of the whole structure of the movement and its adaptation to the conditions of the technological age in which we live. For this reason the wide support which the new business schools have received from industry is encouraging. A report from the Confederation of British Industries, issued in August, appealed for the fullest co-operation from industry in establishing the new Business Schools in Manchester and London, urging that the Schools would not meet the needs of industry without such co-operation.

The Confederation considered that business education has two main tasks. One is the development and teaching of business studies based on such subjects as economics, accountancy, law and sociology, in the same way that education for the medical or legal profession is based on appropriate subject groups, and the application of this knowledge to business. The other task is to develop the personal qualities needed for successful management, and the report suggests that these must include a critical awareness of environment, strong powers of perception, and ability to assess achievement, to take correct decisions, to interpret human behaviour, and to use labour and materials to achieve a specified target. The Confederation also believes that the Schools should serve two groups: besides courses for managers with some years of experience in industry on the threshold of more senior posts, there should be courses for those who have recently graduated.

The Confederation's views are thus closely in line with the views expressed by Mr. McClelland, and the first task of business education appears to be very much what is already being attempted inside the Civil Service at the Centre for Administrative Studies. On the other hand, in some of the evidence to the Estimates Committee in its recent enquiry into recruitment to the Civil Service, some uneasiness was apparent as to the possible effect of proposed methods of recruitment to the Department of Economic

Affairs building up a corps of specialists with too narrow an outlook and range of experience. Government economists of all people will need constant refreshment from outside, and use of the new Business Schools might be one answer. It should not be imagined, however, that the new Business Schools by themselves can meet more than a fraction of the need, important as that fraction may be. Their work will need to be supplemented by the fullest possible use of other facilities for education in management and by a considerable programme of well-planned research, in which field the new Social Science Research Council should in due course make felt its own influence. Beyond this, however, the establishment of the new Business Schools and the wider recognition that the question of education for management is being faced realistically by industry and tackled with determination should have a beneficial effect on recruitment to industry. At the Cambridge meeting of the British Association, Mr. D. W. Hutchings described an enquiry undertaken at the request of the Department of Scientific and Industrial Research in view of the relatively small proportion of engineering graduates who accepted awards to stay on for research. He expressed the view to the Engineering Section that an alarming proportion of our ablest graduates in science were intent on university careers, although in technology, on the other hand, far too few graduates were ready to undertake academic research. Even in arts it appears, however, that industry now has increasing difficulty in obtaining recruits: an increasing proportion of the ablest graduates remain at their university, and those who do leave tend to prefer teaching, the professions or the Civil Service to industry. Clearly there is a problem of priorities which is outside the scope of a discussion of the methods of selection or training for management, but its existence emphasizes the far-reaching importance of a determined and urgent effort to ensure that management in industry and elsewhere is of the highest quality. Its importance for our economic, scientific and industrial effort is decisive, and as management is seen to be efficient its effect on the recruitment of first-class talent could also be decisive. Nor should it be forgotten that in the long run it is on the quality of management in a wide range of spheres that the success of our efforts at national and regional level depends.

LOWER PALAEOZOIC STRATIGRAPHY

Les Temps Fossilifères

Par Prof. Henri Termier et Geneviève Termier. 1: Palaeozoïque Inférieur. Pp. v+690. (Paris: Masson et Cie., 1964.) 270 francs.

BOOKS by individuals about the history of the Earth fall into two categories. The majority are written with the undisguised intention of capturing part of the growing undergraduate market. They are, in the main, unpretentious accounts with a strong regional bias and, despite the advance notices of their publishers, are usually sufficiently restrained in their treatment of the elements of stratigraphy to be freely prescribed to students enmeshed in one's own impressions of the subject. The remainder are much more ambitious theses which, by deployment of detail, contrive to win recognition as definitive works of reference. They appear with increasing rarity, because for several decades now it has been beyond the capacity of any one man to maintain a high standard of scholarship and first-hand experience over so wide a field as world stratigraphy, which explains the modern preference for collaborative works compiled

by several experts. It is therefore with mixed feelings that one opens a volume on Lower Palaeozoic stratigraphy and palaeogeography, even though it has been prepared by H. and G. Termier, surely the most prolific partnership ever known to geology.

On the whole, Volume 1 of *Les Temps Fossilières* well survives a scrutiny, sharpened by a familiarity with the geology of certain regions that is necessarily greater than that of the authors. The Termiers have evidently missed very little background information and the data selected for publication have been marshalled and interpreted in an interesting way. Sixteen time-stratigraphic units have been recognized, and in the sections devoted to each there are chapters on the absolute time range of the epoch, regional stratigraphy, earth movements, igneous activity, sedimentary deposition, palaeoclimates, palaeogeography, palaeontology and palaeoecology and also an extensive bibliography. The text is supported by 124 stratigraphical tables and 441 figures, including well-designed regional maps showing rock distributions and palaeogeographic reconstructions and excellent illustrations of successions, sedimentary features and fossils.

There are, of course, some disadvantages to sorting inter-related observations into such neat pigeon-holes. The interpretations offered within each chapter of a section are concerned with different aspects of the Earth's history during a given segment of time. But since they are all ultimately dependent on the distribution, disposition and characteristics of the same rocks, reiteration can become noticeable and the maintenance of separate chapters (especially on climate, sedimentation and palaeogeography) contrived in some sections. Yet the segregation of information can also be effective. The Caledonian orogeny, for example, does not burst unheralded on the scene as in so many other text-books. The precursory phases as well as the climactic movements are described in their stratigraphic context from one section to the next and their effects are well brought out in the palaeographic interpretations.

In a study as comprehensive as this, some information is bound to show signs of only partial digestion. The tell-tale traps of recording "*Orthis testudinaria*" in the basal Ordovician (p. 308), of using *Dicoelosia* (p. 543) as well as its synonym *Bilobites* (p. 521), of assigning—here and there—genera to the wrong superfamilies, of identifying the Manx Slate as Pre-Cambrian (p. 82) and of finding only "Tethyan" and "Balto-Scandinavian" elements in the Caradocian faunas of Britain (p. 396), suggest some unevenness in textual accuracy. But the most serious criticisms of the study arise from the arrangement and content of the stratigraphical tables and the status assigned by the authors to some of the major time-stratigraphical units.

The stratigraphical tables are so arranged that the successions selected to illustrate the geology of a region are grouped together to show the ranges of named units but not necessarily an accurate correlation of them. Moreover, no standard succession is used to give correlative continuity from one table to the next, so that, in the absence of diagnostic fossils, the tables can become unconnected columns of rock units. This lack of stratigraphical discipline has led to obvious errors. Thus, the Ashby State of North America is, in one table (p. 377), restricted to the zone of *Nemagraptus gracilis*, while members assigned to it by American geologists are, in another table (p. 345), included in the zone of *Glyptograptus dentatus*; the Kosov Beds of Czechoslovakia with *Akidograptus acuminatus* are included in the Ordovician (p. 419); and the "Hirnantian" of Shropshire is equated with the Drummuck Mudstones of Scotland (p. 465). In a review of this scope one would also expect the standard section on which the correlation of a region is based to be invariably given. But this is not so. The Llandovery shelly facies of Britain, for example, are not represented

by successions in the type area but by an imperfect version of the less well-known outcrops in south Scotland.

Finally, one must join issue with the authors for the way they use 'Tremadoc' and 'Silurian' as systemic names. This procedure is unwarranted and creates many more difficulties than it can ever overcome. Their recognition of the discredited Ozarkian as a synonym of the Tremadoc should have arrested any temptation to resolve controversy over the systemic affiliations of the series in this manner. Moreover, to resuscitate Grabau's 'Silurian' as an answer to facies shifts across the generally accepted Siluro-Devonian boundary is to ignore the fact that all stratigraphic measurements of time are man-made and liable to be inappropriate in some succession or other.

A. WILLIAMS

GEOLOGICAL THESIS ON HADHRAMUT

The Stratigraphy and Structure of the Eastern Aden Protectorate

By Z. R. Beydoun. (Overseas Geology and Mineral Resources Supplement Series No. 5.) Pp. viii+107+illustrations and maps. (London: H.M.S.O., 1964.) 27s. 6d.

THE first thing to note about this geological survey is its size, 92,000 square miles (about as big as the United Kingdom); and the second is that such a remote rugged mountain and desert plateau region—virtually unknown before the Second World War—was mapped in fifteen years after 1945. Previously, the only geological exploration had been around the fringes in Yemen, Somaliland, Socotra and the Oman mountains, while the shield and southern half of Arabia remained geologically another 'empty quarter'. The barren limestone plateau north of the Wadi Hadhramut was first crossed by Philby in 1936 and the Mahra territory in 1946 by Thesiger.

In the 1920s and 1930s there were sporadic geological reconnaissances along the coast around Mukalla and into the Wadi Hadhramut, but the first detailed stratigraphic work was done by Wetzel and Morton over 20,000 square miles of Mahra country in 1947–48, close on Thesiger's heels, and also by camel, a very arduous expedition. Dr. Z. R. Beydoun, who spent six consecutive field seasons, 1953–59, in the Eastern Aden Protectorate, was able to use 'Land-Rovers', astrofixes and aerial surveys; but most of the 'main motorable tracks' shown on his locality map did not exist at the beginning, nor were there any drilled wells of potable water.

Having worked on similar stratigraphic sections in southern Jordan and visited the neighbouring countries of Aden, Socotra, Somaliland, Dhofar and Oman, he is particularly well qualified to present this thesis, which is a good example of the high standard of stratigraphical, palaeontological and petrographical work now undertaken by oil companies, even on formations that are only of background interest to oil-finding.

The quality of this publication is also extremely high, comprising 3 loose geological maps in colour and 16 plates (including 3 regional stratigraphic correlations) in 100 pages of text.

For the sake of readers who are not familiar with the many references from surrounding countries, it is a pity that an outline map of the Arabian peninsula was not included. The salt comes should also have been marked on the tectonic map (Plate XV).

The Eastern Aden Protectorate belongs to the foreland or shelf belt surrounding the Arabo-Somali granite nucleus. Pre-Cambrian and probable Cambrian basement rocks—folded and faulted on north-south lines and then eroded—are unconformably overlain by basal sands, limestones and marls with local evaporites of Middle-Upper Jurassic age.

This big unconformity is regional for western and southern Arabia from Yemen and Aden to Dhofar. Fossiliferous Cambrian is known only from the Dead Sea, where it is followed by marine Triassic. Oman and eastern Saudi Arabia have marine Palaeozoic and Triassic below the transgressive Jurassic. The Eastern Aden Protectorate Jurassic is highly fossiliferous and its evaporites have given rise to salt domes on the western frontier with Yemen. Dr. Beydoun considers the salt to be of Jurassic age and diapiric in action, contrasting with the accepted Cambrian age of the Oman piercement plugs and the Miocene age of the Red Sea ones.

I was struck by the anomalous trend of the evaporite facies line in this area, west-north-west-east-south-east, the same as the faults among which the domes are located, and wondered if there was a genetic connexion.

The facies lines of the rest of the Jurassic and of the Cretaceous are north-south from Saudi Arabia to Somaliland. The Jurassic of the Eastern Aden Protectorate and Yemen correlate well, including the evaporite facies.

The Cretaceous consists of sand in the west and limestones and marls in the east, and this period and the succeeding Tertiary one of limestones, shales and evaporites are subdivided into litho-stratigraphic units which are described in detail with faunal lists and regional correlations.

The dominant structure of the Eastern Aden Protectorate is the gentle east-west geo-anticlinal Hadhramut arch in Palaeocene limestone forming a plateau between the sands of the Rub-al-Khali and the Gulf of Aden.

There is no space in this review for the controversial rift-fault tectonics which dominates the last twenty pages on structure, especially as Dr. Beydoun quotes fully many publications on neighbouring areas. In conclusion, he and his sponsors (Iraq Petroleum) are to be congratulated on a very valuable contribution to the geology of this remote region. He and his assistants and colleagues deserve high praise for their strenuous and painstaking field mapping under adverse topographic conditions—well illustrated in the photographs. F. E. WELLINGS

A USE FOR MATRICES

The Matrix Analysis of Vibration

By Prof. R. E. D. Bishop, G. M. L. Gladwell and S. Michaelson. Pp. x+404. (London: Cambridge University Press, 1965.) 100s. net.

THE Matrix Analysis of Vibration is basically mathematical and it treats the subject of matrices in a much more general manner than might be associated with the title's particular association of it with vibration. The nature of the answers to many of the numerous examples makes this clear, but others show that the reader is recommended to do a fair amount of numerical computation in order to ascertain the tenacity of his grip on the process of practical application of matrix methods and also no doubt to give him some idea of the tedium and irritation that are liable to be found in long calculations that are unavoidable in solving certain types of vibration problem.

As the first step in making calculations in connexion with vibration of any actual system, simplifying assumptions are used in representing the physical attributes of the system by symbols or numbers. Out of these it is usually possible to build an equation or equations. The next stage is the purely mathematical one of solving the equations, and it is with this stage that this book is almost wholly concerned.

As the matrix method is not applicable to a system with an infinite number of degrees of freedom (and strictly, this means every system) the book considers in some detail the problem of determining the dimensions of a "lumped-mass" system closely equivalent to the actual system. The

labour of solving the equations is then left to a digital computer. It is odd to recollect that before such aid was readily available, lumped mass systems were sometimes replaced by distributed mass systems in order to ease calculation by the conventional methods of the time.

Mention is made of the fact that where the equation representing a vibration problem is found to be highly sensitive to small changes in the arguments, the physical system is likely to be correspondingly temperamental. If it is, close prediction of its behaviour is impossible and so meticulous calculation may be purposeless.

The note on p. 227 that two methods of calculation give results differing by only 0.645 per cent inspires the remark that a discrepancy of ten times that amount is gratifyingly small in quantitative predictions of torsional vibration in some practical cases. This is, perhaps, not a valid comment in reviewing a book that is avowedly mathematical and that deals very clearly and very thoroughly with the principles and practice of using matrix methods for solving linear equations with large numbers of unknowns.

The question as to whether any particular vibration problem can be solved with adequate accuracy and speed without resorting to matrix analysis is usually one that demands attention from both the engineer and the mathematician, if it is asked at all. Whatever the answer may be, calculation in practice is preferably carried out in at least two different ways, even if none of them is rigorous, in order to obtain some safeguard against gross errors.

W. A. TUPLIN

PROGRESS IN MAGNETISM

The Theory of Magnetism

An Introduction to the Study of Cooperative Phenomena. By D. C. Mattis. Pp. xvi+303. (New York and London: Harper and Row, 1965.) 86s.

Physics of Magnetism

By Prof. S. Chikazumi. English edition prepared with the assistance of Stanley H. Charap. (Wiley Series on the Science and Technology of Materials.) Pp. xii+554. (New York and London: John Wiley and Sons, Inc., 1964.) 120s.

HISTORIES of physics and magnetism have much in common, beginning with the discovery of the lodestone by the Greeks. Modern texts on magnetism tend to overlook the work of past philosophers and it is very refreshing to find such an excellent account of the past introducing the main text of the first book.

A student fresh to the theory of magnetism is confronted with literature of alarming proportions. *The Theory of Magnetism* attempts to organize this material by treating magnetism essentially as one of the most important examples of co-operative phenomena. The emphasis throughout is on strong interactions between two or more particles and especially those between electrons and spins. The book itself begins with a review of the quantum mechanical idea of exchange and discusses various concepts derived from it. Magnetic moments are measures of angular momentum, and thus a detailed quantum mechanical discussion of angular momentum is given. Important relationships, formulae and tables are presented in an unorthodox but very attractive way. Many electron wave-functions complete the mathematical basis of the theory and most of the more important theorems and rules are clearly presented.

Spin waves form the principal topic of the book, and thus a study of the statics and dynamics of magnetism follows. It commences with a semi-classical treatment and leads to the introduction of magnons and concludes with spin waves in insulators. Magnons in metals are treated separately and are derived from detailed discussions of the properties of electrons in metals. The third and final

part of the book deals with the effects of temperatures on spin systems, and consequently the thermodynamics and statistical mechanics of magnetism are considered. Phase transitions and the Ising model are discussed at length. Tables for indirect exchange theory form a very useful appendix and the book concludes with a complete and up-to-date bibliography of collateral reading.

Magnetism is far from all theory, and this is clearly emphasized in the *Physics of Magnetism*. A general and fully comprehensive review of magnetism is presented with an emphasis on physical concepts. One departure from common practice is the use throughout of the MKSA system of units, although the treatment is as non-mathematical as possible. The book begins with a classification of magnetic substances and then describes the properties of a ferromagnetic body. Theoretical background for the origin of magnetism and the theories for ferromagnetism and ferrimagnetism form the second part of the book. The discussion tends to be pictorial, and the reader needs little in the way of quantum mechanics. The book is centred around magnetic domains, and a fully comprehensive discussion of this concept is given with numerous figures and photographs. The domain concept is extended to account for the various observed magnetization processes, and many detailed results and conclusions are presented. More specialized topics form the last part of the book—some of the more important topics discussed are induced magnetic anisotropy, the ferromagnetism of thin films, thin wires and fine particles, various magnetization phenomena, the rare earth metals and also techniques for investigating internal magnetic structure. Probably the most important aspect of magnetism concerns its technological application, and this is not forgotten with a brief discussion of the types of magnetic materials and special applications of them. Data relating to magnetic substances are collected in an appendix.

In my own opinion, both books are most successful in their intending aims. *The Theory of Magnetism* is intended for the research worker, and caters particularly for the theoretician. The major achievement is to step from most complicated situations to accurate arguments with simple explanations only. The style of the book is unconventional and many topics are presented in a textbook for the first time. *Physics of Magnetism* is pitched on a somewhat less-advanced level as it caters for undergraduates as well as research workers. For an experimentalist, it contains most of the important facts appertaining to magnetism and contains lucid explanations for them. Both contain numerous problems for the reader to test his knowledge and its applications. There is little material common to both books and together they cover most of the field of magnetism. They are both attractively presented and may be recommended with confidence.

C. A. BATES

ANALYSIS OF SURFACE-ACTIVE AGENTS

Identification and Analysis of Surface-active Agents by Infrared and Chemical Methods

By Prof. Dieter Hummel. Translation by Dr. E. A. Wulkow. Text Volume. Pp. xiv + 386. Spectra Volume. Pp. 166 (466 spectra). (New York and London: Interscience Publishers, a Division of John Wiley and Sons, Inc., 1964.) 150s. the two volumes.

PROF. HUMMEL'S work on the systematic identification of surface-active agents from their infra-red spectra was reported at the third International Congress of Surface Activity in 1960. His book, first published in German in 1962, contains a much expanded version of his own work as well as chemical methods for the identification of surfactants, which were added in order to broaden the analytical character of the book.

Identification and Analysis of Surface-active Agents by Infrared and Chemical Methods is the translation, without modification, of the earlier book and hence the literature is covered only to 1960. In the area of detergent analysis, as in most other fields of research, progress has been notable and rapid in the past 5 years, and thus much of the content of the book is out of date. For example, gas liquid chromatography is mentioned only once and thin-layer chromatography not at all. For this reason, the book fails in the author's expressed intention of providing a general book on detergent analysis. It remains, however, an extremely important reference volume for the detergent analyst and will be particularly useful in the identification of little-known actives.

A comprehensive list of surfactants (or 'tensides' as the author proposes all interfacially active materials should be called) is reviewed systematically with copious notes on methods of manufacture, physical properties and infra-red spectra. This chapter (141 pages) and the volume of spectra form the useful content of the book. The introductory chapters on structural characteristics of surface-active agents (13 pages) and the determination of the electrochemical behaviour of surface-active agents (12 pages) are oversimplified and contain a number of errors. For example, the cationic character of amine oxides in aqueous solution is ascribed to the formation of free amine by hydrolysis. In fact the cationic species present is the conjugate acid of the amine oxide.

The later chapters on chemical methods for determining the structural characteristics of tensides (24 pages) and methods for the quantitative analysis of tensides (37 pages) suffer most from the omission of recent research. This is unfortunate since there is no good modern review of the analysis of mixtures of surfactants which can aid the detergent analyst.

The tables at the end of the book (114 pages) summarize much of the information given in the text. Most of them are useful but one should question the value of recording in tables the results of empirical tests (for example, the Wurzschnitt reaction with iodine) which cannot be used with confidence for the identification of specific materials.

The volume of spectra is well produced and peak positions and intensities are easily read direct from the figures. The text volume is printed in Times Roman type on good quality paper and both volumes are well bound. The translation is adequate but suffers from literal translation in parts. The lack of typographical errors in the whole work is notable. The book costs £7 10s. which, combined with the lack of new information it contains, will prevent its use in all except specialist laboratories.

P. ROBSON

LEATHER ANALYSIS AND TESTING

The Chemistry and Technology of Leather

Edited by Fred O'Flaherty, William T. Roddy and Robert M. Lollar. Vol. 4: Evaluation of Leather. (American Chemical Society Monograph Series, No. 134.) Pp. viii + 440. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1965.) 17.50 dollars; 144s.

THE publication of Volume 4 of the American Chemical Society Monograph Series No. 134, *The Chemistry and Technology of Leather*, completes the Series begun with the appearance of Volume 1 in 1956. As in the previous volumes, each chapter is contributed by one or more authorities in the particular field, but in this volume all the authors have been drawn from the United States. Included in the volume are the analysis and assessment of raw materials and finished leather, including physical test methods. A valuable chapter on fungal resistance of leather has been contributed by T. C. Cordon of the Eastern Regional Laboratory of the U.S. Department of

Agriculture. The chapter on leather finishing by R. Shaw, drawing on his experience with the Rohm and Haas Co., is out of place in the present volume. It is also more discursive and qualitative than is required in a monograph.

It is unfortunate that analytical and physical testing methods for leather are still not co-ordinated by a single body. The commissions of the International Union of Leather Chemists Societies have been particularly successful in securing agreed physical test methods which many countries are adopting and have also made progress with chemical analytical methods. The American Leather Chemists Association (A.L.C.A.) has, however, continued to develop methods independently. This division is reflected in the various chapters of this book, with often a disproportionate emphasis on the A.L.C.A. methods.

The discussion of analytical methods, particularly when their basis is largely empirical as is often the case with leather and its raw materials, does not make easy reading. Nor is the quotation in full of an A.L.C.A. method justified. A fuller discussion of the accuracy needed in the various determinations would have been valuable, compared with that provided by the methods given.

The chapters on physical testing have greater general interest, especially that by Mieth Maeser on dynamic and non-destructive testing, which refers especially to shoe leathers and their performance.

The American Chemical Society's leather monograph first appeared under the authorship of J. A. Wilson, who presented a coherent and forceful point of view, in some instances outlining approaches only recently being taken up again. The change to the present multi-volume form, with a wide array of authors, has necessarily resulted in the loss of unified consideration. The chapters have varied in merit and value more than is usual in a book of this character, but this reflects the limited number of persons making significant contributions to leather science and technology. Despite the faults, to which reference has been made, access to the final volume and to the whole work will be a necessity for all seriously concerned with leather, although their use of them will require that they be discriminating.

A. G. WARD

APPLIED ECOLOGY

Ecology and the Industrial Society

Edited by Gordon T. Goodman, R. W. Edwards and Dr. J. M. Lambert. (A Symposium of The British Ecological Society, Swansea, 13-16 April 1964.) Pp. viii+395. (Oxford: Blackwell Scientific Publications, 1965.) 70s. net.

AMONG the outstanding questions raised by this, the British Ecological Society's fifth symposium volume, is the future of ecology as a source of practical guidance for the management of our man-dominated environment. Although the Society has, by the publication last year of the *Journal of Applied Ecology*, asserted that ecology has such a role, the sixteen articles in this volume are not unanimous on this point. In his opening address Prof. Clapham advocates the direction of university research towards increasing biological productivity and providing a scientific basis for conservation policy, a view that is supported by Britain's full backing of the International Biological Programme. This view is also implicit in suggestions by several authors that reclamation policies are far too empirical and lack a basis in theory. The opposite view is ably put, however, by Hynes, who claims that, in the field of water pollution, the scientific knowledge already exists and that current problems are nearly all in the fields of administration and politics. That such differences are not solely due to differing progress in different fields is indicated by Hawkes's views that, in the closely related field of sewage treatment, many fundamental ecological problems remain.

In fact a striking characteristic of many papers in this collection is the revelation of interesting fundamental problems at the root of purely practical investigations. A few examples are: (a) Bradshaw's demonstration that extreme conditions in contaminated environments can facilitate the study of high-speed population evolution and that conspecific plant populations have rigid spatial boundaries in contaminated ground; (b) Hawkes's views on the effect of temperature on turnover and biomass of sewage decomposers and the stimulation of bacterial activity by grazing animals; (c) Templeton's stress on the need for food chain studies of marine pollution by atomic wastes (consumption of *Porphyra* (laverbread) in Swansea limits waste disposal from the Windscale plant in Cumberland), and his demonstration that radionuclides in the sea sink or float according to their role in phytoplankton physiology.

There are, however, many points of more immediate practical importance: Hynes contends that much routine toxicity testing is a waste of money because the laboratory tests used are not related to survival in Nature; Moore concludes that we have now reached the time when fish for human consumption should be monitored for organic chlorine residues; Hawkes believes that sewage treatment in many places to-day is inferior to the best practices of the Assyrians and the Babylonians, and that diseases such as bovine cysticercosis are on the increase as a result; Gilbert's demonstration that the species range of lichens provides a practical method for detecting air pollution.

This is a well-edited book, well provided with indexes and well illustrated; the only error which seems important enough to mention is the maximal figure (p. 249) of "900,000 invertebrate animals per m² of soil"; this must surely apply to arthropods only, for nematodes occur in their tens of millions and Protozoa in far greater numbers. Inevitably the volume contains highly specialized papers in which little attempt is made to relate the material to the rest of the symposium or explain its significance, although these are far fewer than in many such volumes. The custom of publishing all papers read at meetings (and presumably chosen by the editors in the first place) is well established, but it costs editors' time and readers' money; perhaps future organizers might reserve the right at the outset to publish only a proportion of the more successful papers.

A. MACFADYEN

'STRASBURGER' REVISED

Strasburger's Textbook of Botany

Rewritten by R. Harder, W. Schumacher, F. Firbas and D. Von Denffer. New English Edition from the Twenty-eighth German edition. Translated by Peter Bell and David Coombe. Pp. xvi+846. (London: Longmans, Green and Co., Ltd., 1965.) 84s.

THE publication of a new English edition of *Strasburger's Textbook of Botany* is an important event for many English-speaking students of the subject. Most pre-war students of botany were well acquainted with the previous English edition, published in 1930, but in the absence of more recent translations of the later German editions, it is scarcely surprising that 'Strasburger' is not so well known to modern students. Eleven German editions have appeared since the last English edition and the present translation is from the twenty-eighth German edition, published in 1962.

As in previous editions, four well-known authors deal with the principal aspects of botany: D. Von Denffer with morphology, W. Schumacher with physiology, R. Harder with lower plants, and F. Firbas with seed plants and plant geography. The whole is a remarkably comprehensive account which provides a valuable introduction to almost all aspects of botanical science.

Some botanists have questioned the value of extensive compilations of this kind and prefer shorter accounts of

selected aspects of the subject. This approach, however, carries the danger, which is undoubtedly a feature of certain modern botany courses, that the student may be well informed on recent spectacular advances in such topics as plant physiology, biochemistry, fine structure and especially those aspects collectively described as "molecular biology", but may have virtually no knowledge of other aspects of botany, which are less fashionable, but equally important to a thorough understanding of the plant. The new edition of *Strasburger's Textbook* is a timely corrective to such a restricted outlook. It deals in detail with various topics, such as morphology and the physiology of growth and movement, which are rarely adequately treated in general text-books. It is true that it is difficult for so broadly based a work to keep abreast of present developments in rapidly advancing branches of botany. But with the present spate of specialist volumes and semi-popular journal articles there is little risk that the more recent advances will be overlooked by the enquiring student. The merit of a work such as 'Strasburger' is that it provides a reasonably up-to-date account of the established facts and principles of botany, which, in the words of the translators, will equip the botanist "not only to deal with the theoretical and practical problems of to-day but also to formulate and solve those of to-morrow".

The individual parts of the present edition are all of considerable merit. The section on morphology describes some of the principal discoveries in the fine structure of the cell, but is above all a thorough account of the form and structure of plants. The critic may object that there is little reference to modern experimental studies of morphology, but the results of such work are perhaps still somewhat controversial and require more detailed discussion than can be accommodated in a general text-book. In the physiology section, the parts dealing with metabolism appear to be up to date, at least so far as respiration and photosynthesis are concerned, although our knowledge of the role of nucleic acids in protein synthesis has advanced considerably since this 1962 edition. The physiology of growth and movement is well covered. This section was published late enough to include a treatment of gibberellins, but too early to include an account of phytochrome.

In the systematic section, only seven major divisions are recognized although the authors point out that bearing in mind the purposes of a text-book certain simplifications have been made intentionally. Apart from the Cyanophyta, which are rightly placed in a separate division, all the algae are included in a single division Phycophyta, but this false impression of unity is corrected later by a diagram emphasizing the independent origin of the principal algal groups. With so extensive a field to cover it is inevitable that much should be omitted, but many interesting details are described, and in the part devoted to diatoms there is an up-to-date account of the sexual reproduction of both pennate and centric diatoms. The section on seed plants is very condensed but gives a broad survey of the principal orders. The concise account of plant geography includes a short review of the plant communities of central and north-west Europe.

A useful set of references covers each major section of the work and has been added to since the 1962 German edition. Even certain useful books published in 1964 are included, for example, *The Structure and Life of Bryophytes*, by E. V. Watson.

For a comprehensive text-book, 'Strasburger' is remarkably readable and both authors and translators have done their work well. Although described on the verso as covering the work of students in their final year at school, at technical colleges and in the first years of universities, it is far more than an introductory text, and most botanists would benefit from having 'Strasburger' readily available on their shelves. It is well illustrated and produced and at 84s. is very good value indeed.

A. ALLSOPP

PHYSIOLOGY OF PLANTS

Encyclopedia of Plant Physiology

Edited by W. Ruhland. Vol. 15: Differentiation and Development, Part 1: Pp. lxiv+1647; Part 2: Pp. xliii+1362. (Berlin, Heidelberg and New York: Springer-Verlag, 1965.) Ganzleinen DM 748; Subskriptionspreis Ganzleinen DM 598.40.

THE publication of a scientific treatise comprising 70 chapters written by 53 authors and consisting of more than 3,000 pages is a notable achievement, even in times when the breaking of records is an almost everyday occurrence. When, furthermore, we realize that the two books form only the latest two-part volume of the famous *Encyclopedia of Plant Physiology*, which has been appearing in parts in recent years, we must be still more impressed by the sheer mass of data concerning the life-processes of plants that have been accumulated.

The new volume covers the all-important branch of plant physiology that passes under the general title of "Differentiation and Development". The title itself, however, scarcely indicates the range of topics that are covered, for the authors have set out not only to summarize what is known about the structural and physiological changes that are involved in the life of the plant, but they also enter into the field of cytology and genetics sufficiently to indicate how growth and differentiation are basically controlled by genes.

The editor, Dr. Anton Lang, says in his introductory essay that: "he has misgivings that the volume, in times to come, may be considered as the last major monument—not to say epitaph—of an era to which future generations of biologists will refer, with a mixture of condescension and (at least we hope) nostalgia, as the dark ages of developmental physiology". He takes this dim view because the recent outstanding advances in genetics seem to him to keep other branches of biology somewhat in the shade. He continues, however, in a more hopeful vein when he says: "Genetics and developmental physiology are theme and countertheme. The objective of genetics is to understand how the hereditary information of organisms is written, that of developmental physiology, how it is read". He also expresses a hope that the unveiling of the 'genetic code' will help to throw further light on the connexion between the two disciplines.

It is impossible to summarize the contents of the volume very adequately in a few words. It must suffice to say that the treatment is many-sided and very comprehensive. We can, for example, read about the physiology of abscission, seed dormancy and germination, graft hybrids, photoperiodism, auxins, fasciation, as well as about abnormal differentiation caused by fungal invasion and attack by insects or viruses. We can learn such practical details as that seeds can often be more effectively stored in sealed tin cans than in the time-honoured paper packet. On the other hand, we can pass on to the complexities of correlation in plant development. The volume ends with German/English and English/German indexes to the subject-matter and there is a third index to authors. Literature is cited at the end of each chapter.

The printing and lay-out of the book are very good. There is some overlapping of subject-matter as, for example, on pp. 175 and 348 of Part 2 respectively, but this is almost unavoidable in such a large volume, written by so many authors. All readers will be indebted to the authors and editor for bringing together and summarizing such a wealth of information in a readable form. It is to be feared, however, that the very high price of the volume will make it less generally available than it deserves to be. This is a fault that should be avoided especially as it is most desirable for the existing knowledge of this rapidly advancing subject to be disseminated widely before it is out of date.

C. R. METCALFE

UNIVERSITY OF KHARTOUM, SUDAN

SILVER JUBILEE OF THE FACULTY OF AGRICULTURE, SHAMBAT

By PROF. M. A. NOUR

Dean of the Faculty

IN early December 1965 the campus of the Faculty of Agriculture of the University of Khartoum will welcome distinguished guests from most African countries, and from many institutions elsewhere, all of whom are intimately concerned with agricultural education at university-level, and each eminent in the field of his own interest. The Food and Agriculture Organization of the United Nations has kindly agreed, at our invitation, to hold concurrently an Inter-African seminar to discuss "The Role of Faculties of Agriculture in Developing Societies". Most of the participants, invited from some twenty-four African countries, will be from among those who are playing a leading part in policy and decision-making in agricultural higher education and planning in their respective countries. Thus the Faculty will open its doors, to share a happy historical occasion during the celebration of its twenty-fifth anniversary with men of eminence in the field of agriculture, and will participate with them in the discussions at the seminar.

On such occasions it is pertinent to indulge in some introspection, on one hand, and speculation on the other. In 1957 my predecessor, Prof. R. J. McIlroy, gave an account of the Faculty at that stage of development¹, but since then nothing has been written on this score for readers outside the Sudan. What follows, therefore, is an endeavour to bring the information on the structure and function of the Faculty up to date.

The Faculty in 1957 consisted of three departments, with a total staff complement of eleven; now there are eight departments and thirty academically qualified personnel. The Faculty is now composed of the Departments of Agricultural Botany, Agricultural Engineering, Agronomy, Animal Production, Biochemistry and Soil Science, Crop Protection, Horticulture and Rural Economy. Eight years ago there were three Sudanese

and eight expatriate lecturing staff; now the number of Sudanese is twenty-four, all of whom have received a Ph.D. degree from universities in the United Kingdom or the United States. Six more are abroad at present and will join the staff on their return within the coming three years. The number of undergraduate students in 1956-57 was 39; now it is 167. And in 1957 no post-graduate training was available, although the Faculty was becoming keenly conscious of its role in this field, and a comparatively small but sound research development was in progress. Since then, 10 candidates have obtained their M.Sc. degrees here, 10 more are working towards it, and two are registered for the Ph.D. course. From 1938 (when the Faculty started) to 1957 some 20 publications appeared in international journals or as books, whereas more than 90 publications of comparable scientific standing have appeared since then. Because the Faculty in 1957 was just emerging, the scattered nuclei of research activities were then novel developments, whereas research is now in progress in almost all the disciplines of agriculture with perhaps the greatest momentum on the production and protection of cotton, sorghum, millet, broad bean, winter vegetables, forage crops and citrus. Nutrition of poultry and large animals and their breeding and adaptability are being investigated, while problems of salinity, irrigation and fertility of heavy clays are receiving attention by members of the Soil Science and Engineering Departments. The Faculty has become increasingly conscious of its geographical location, in relation to the Sudan and Africa, and this has led to a concerted effort in the past few years to co-ordinate team research on short-term, as well as more far-reaching, investigations of dry-land problems. To go further would be to submit a research report, but a *Jubilee Bulletin* of the Faculty will be published, available on request, containing details of present trends in research and a list of all published work.

Fig. 1. Façade of the main building of the Faculty of Agriculture, University of Khartoum

The physical capacity of the Faculty has been greatly increased by a building programme which cost about £S.150,000, excluding a corresponding expansion of hostels, which house all the students, and the rapidly growing annual budget. A generous grant from Barclays Bank of £S.30,000 is allocated for building a new Department for women students to study home science and community development, the intake for which is planned to start in 1966-67. In addition the Rockefeller and Ford Foundations have donated 107,000 dollars and 75,000 dollars, respectively, towards the cost of research and improved teaching facilities in the Faculty.

The reference library at Shambat (which also serves the Faculty of Veterinary Science) has increased almost tenfold in book and journal accessions, and now houses some 25,000 volumes and more than 500 journals, apart from considerable stocks of standard text-books available in departments for borrowing by the students. Other faculty service facilities have been added since 1957, such as a plant environment control unit and a tropical shade house costing some £S.30,000 to erect, an agro-meteorological station which contains examples of virtually all the instruments available for recording soil and atmospheric climatological data, and a photographic unit. The recently established isotope research unit is bound to initiate new approaches towards agricultural problems under dry-land and irrigated conditions. There are two farms, which are in increasing demand for demonstration and experimental purposes, although the controversy over the functions of a university farm is as lively as ever.

The structure of the undergraduate courses has also undergone far-reaching changes. The old system, based on two years in the Faculty of Science and three years in the Faculty of Agriculture, has been re-modelled, and now involves one year in the Faculty of Science and four in the Faculty of Agriculture, the latter being devoted to basic and general topics for the first three years, leaving the final year for some degree of specialization. While we have been primarily concerned with the design and detail of a new type of final year, course structures in the preceding three years have also been reviewed to provide a logical yet attractive sequence in the framework, content and functional inter-relationship of these courses. This has been done and has, with remarkably few modifications, withstood the test for the past three years.

The final-year course is of an honours nature (implying a greater degree of specialization in one discipline rather than a particular level of excellence in the examination). In order to produce graduates with a measure of competence in one of the many branches in agricultural science, there was obviously the possibility of recommending a single-discipline specialization in the final year, thus offering a 'special' degree following the pattern of the University of London. This avenue was explored, but the academic hazards involved (not to mention the financial implications) became abundantly clear and single-subject specialization has been left, as in the past, to the postgraduate level.

The design of degree that has been found most appropriate for the requirements of a developing society is based on a combination of selected courses in the final

year, with the choice of discipline as the main option but with four additional supporting (ancillary) courses from other departments. The commitment of these supporting courses in formal time-table hours is the same as for the main option, namely, eight hours in total; but a student is expected, in addition, to submit a short dissertation in a subject of his choosing.

In recommending this structure, and now for the first year testing it, the Faculty has been keen to achieve a higher plateau in intellectual and academic activities than at the general degree level. The 'group specialization' design of the courses not only brings the teaching staff of each department closer together for purposes of co-ordination (such as in seminars and study groups), but will also strengthen the links within and between departments to a much greater extent than has hitherto been the case.

The main objective is to attempt to produce young men and women: (1) adequately aware of the underlying scientific and social principles governing agriculture; (2) with a good measure of competence in their grasp of the principles and practices of crop and animal production, together with (3) developing a special interest in one agricultural science, though by no means exclusively specializing in it. Thus we have avoided exclusive specialization even in the final year, unlike many faculties of agriculture in other countries, where the last one or even two years are devoted to one discipline only. Presumably this reflects the needs of those countries for specialist graduates from the first degree; but so far as can be assessed, the Sudan and other developing countries will continue to need graduates in agriculture with a fairly broad background.

The underlying major fault in the general degree in agriculture was that it tried to cover a wide range throughout and in a continuously expanding array of disciplines. Two cracks are bound to develop in any such structure. Members of an expanding staff, each with his own speciality, claim a *de facto* recognition by demanding their individual shares of the teaching time-table, which may well lead to interdepartmental stresses and jealousies. The second crack is that, as a result, the students become bored and bogged down, and often lose any interest that may originally have sparked their imagination towards agriculture. Some years ago a student described our courses as the "stuff that makes the head", consisting of approximately equal portions of skin, bone, cartilage, fat, grey matter and nondescript tissue thrown together in the stew. He concluded: "it tastes queer".

After lengthy and intense discussions, and tense moments of conflict, the staff of this Faculty became convinced that we must follow this new 'group specialization' route, which gives a wide coverage in the first three years, perhaps with a "queer taste". But the final year, handled with imagination and confidence, may well achieve the objectives it is designed to serve. It provides more time for students to think, read and enjoy their respective subjects. The educational commandments quoted by Whitehead in order to guard against mental dry rot, "Do not teach too many subjects" and "what you teach, teach thoroughly", are, we hope, followed in this final

Table 1. YEARLY INTAKE OF STUDENTS FROM THE FACULTY OF SCIENCE INTO THE FACULTY OF AGRICULTURE AND NUMBER OF GRADUATES

year. Judging by the appearance of the present final year students, one certainly sees more eyes with sparks in them than previously; but it is still too early to form an objective opinion on whether we have satisfied both the tastes of the student and the needs of the country.

On the occasion of our twenty-fifth anniversary one must ask whether this Faculty is serving the needs of the country efficiently and purposefully. Are we going at the right pace in the right direction, usefully employing all the available manpower resources? Other things being as they are, the Sudan (and indeed Africa) will remain agrarian for some time to come, and graduates in agriculture will continue to hold posts of leadership in the agricultural sector. A Faculty of Agriculture in Africa must serve as a catalyst to speed up the reaction between new ideas and old ones. 'Tradition and Change' has been the theme of many a formal and informal gathering, but the role of the Faculty of Agriculture in this debate has never been brought fully into focus. We are on the march, but one wonders at times of introspection whether, like the march of dons in medieval ceremonial robes at graduation day, our march forward is colourfully academic but of little benefit to the agrarian community. On the whole, universities in Africa have much less contact with their own people than with the West, that has offered to graft a university system of its own pattern on to our African stock. Even if this state of affairs can be relaxedly tolerated in the sphere of chemistry and medicine, it has to be critically scrutinized every now and then—say, at least every twenty-five years—in the domain of agriculture, where science is drawn most closely into contact with the everyday needs of man. In Africa the needs of man are elemental, and so the value of scientific findings for stimulating rural development must logically be scrutinized. Earlier it was said that in the past decade some ninety publications by the Faculty staff have appeared in the international journals. But let us be frank about these publications—they have been effectively transfixed in print, they helped some of us admirably (including myself) to obtain a higher status and income, but on the whole they have remained inert entities rather than activating catalysts. Perhaps here lies one of the main weaknesses of the Faculty *vis-à-vis* the community. The system of the land grant college of the United States has often been suggested as more suited to our needs, involving closer co-ordination between the researcher, the teacher, the planner and the farmer.

Agricultural publications in Africa tend to meet many obstacles before they can even reach the farmer. The concept of the 'agricultural inspector' has prevailed for too long to allow the 'agricultural adviser' elbow-space. Graduates of agriculture have believed that their function was to wield authority (they even until recently dressed in khaki) rather than to teach and extend, and it is significant that courses in extension and management have not yet been introduced in most African Faculties. Agricultural extension, as a systematic and studied plan of campaign, is a new service in the Sudan, and the Faculty has certainly not yet played its full part in leading the minds of the graduate, and hence the policy and decision makers of the future, towards the concept of extension rather than inspection.

Schultz states that: "To produce an abundance of farm products requires that the farmer has access to and has the skill and knowledge to use what science knows about soils, plants, animals and machines. To command farmers to increase production is doomed to failure"³. The role of the Faculty in extension has not yet received sufficient attention, although this is a vital question because Africa now, more than ever before, needs effective extension services.

Africa is an agricultural continent, under-populated except around the main rivers; its peoples depend mainly on subsistence production; and its rains are mainly seasonal and confined to a small portion of the year.

Moigs estimated that 42 per cent of Africa is arid and 22 per cent semi-arid, the remaining 36 per cent receiving adequate precipitation. Twenty-six countries in Africa have large tracts of land classified as dry⁴. Dekker states that only 16 per cent of the African population lives in areas of adequate (over 1,500 mm) rainfall⁵. Of the whole population in Africa (some 120 million people), it is estimated that only about 7.5 per cent live in cities of 200,000 inhabitants, and most of the remainder are agriculturists or nomads depending on a dry-land pattern of subsistence. In the hot arid regions, evapo-transpiration losses are much higher than in cooler climates, and irrigation is essential if the subsistence-level is to be raised as a result of cash cropping and profitable animal production. Modern concepts and technologies in agriculture must be made available to the farmer in order to obviate the elemental hazards and make progressively higher targets possible in production and marketing. Sociology and economics must be harmoniously utilized, as well as the physical and biological sciences, to improve agriculture in Africa.

The role of the graduate in agriculture is paramount, in both planning and execution, yet the Faculties of Agriculture in Africa have not, I think, fully exercised their capabilities and accepted their responsibilities in this context. Let me hasten to add that I do not wish to see the Faculty encroaching on the equally important role of farmer training schools and institutes of agriculture of sub-university level. That would obviously be disastrous and undesirable. Let me further add that a relatively young institution cannot assume greater tasks than it can effectively shoulder without frustration and confusion. But the Faculty, in its natural process of growth, needs to be fully aware of what the community expects from it. What I have said here is neither profound nor new, but is it not often true that the obvious is not said and gradually forgotten? What does the community want us to do? It wants more and better graduates, and it wants more and better planned research, the results of which are more easily taken into the service of the rural community.

The number of Faculties of Agriculture and their graduates in Africa, excluding the United Arab Republic, is pitifully meagre, a total of some 20 or 25, each producing an average of 20 or 25 students a year. The Ten Year Plan of Economic and Social Development of the Republic of the Sudan foresees, on the conservative side, a need for about 1,000 trained administrators, research workers and professional agriculturists by 1972. At the present rate of development this Faculty can only hope, at best, to produce an additional 500 by that date. Thus in terms of numbers we shall be unable (despite our modest achievements) to satisfy the needs of the community, because development is necessarily limited by socio-economical, historical and geographical factors. In terms of quality, we aspire to give the best we can afford. We hope to graduate men and women with a spark of original interest in their profession; but the Sudan and the rest of Africa, not to mention the world, still tends to regard the agricultural 'profession' with guarded zeal in years of economic distress, and with an indifferent yawn when the rains are good. Disastrous fluctuations in yield of crops and pastures in this vast continent are so common that there is little recognition of the value of our service by the peasant and the nomad, a tiresome, vicious circle which will have to be broken in time by education at all levels. The Faculty has a role by developing a sense of pride, enthusiasm and dedication in the profession, both in staff and graduates.

The Faculty of Agriculture has, therefore, plenty of problems ahead, and yet it has not been unsuccessful in its first twenty-five years. It is the oldest of the agricultural Faculties in Africa, excluding one or two in the United Arab Republic and South Africa, and it is keenly aware of its geographical position, in the centre of an arid

zone and at the northern tip of the Gezira Scheme, one of the largest and oldest irrigated schemes in Africa. This Faculty has planned to develop its courses and its researches along lines which are compatible with the typically arid African environment in which it is so aptly situated.

SOCIAL AND INDUSTRIAL GERONTOLOGY IN GREAT BRITAIN

By C. E. FLEMING

Lecturer in Social and Industrial Medicine, University of Sheffield

Community Reactions to Population Ageing in Great Britain

THE 1949 *Report of the Royal Commission on Population*¹ outlined the demographic situation in Great Britain and presented a challenge. "... the ageing of the population of Great Britain ... has been steadily in progress since about 1891 ... it must be expected to continue in the future ... it represents the delayed effect of changes which we have neither the power nor the desire to reverse, and to this extent the appropriate attitude must be not 'must we try to prevent this?' but 'how can we best adjust ourselves to it, so as to minimize the disadvantages and make the best use of any opportunities which it presents?'" (p. 111). One of the most outstanding features of a Western society is the inadequacy of its investigations of later ageing (especially for the sociological, psychological and related sciences), of applying research findings in social and industrial life and in basic organizations and institutions which would be the foundation for such thought and action. This is particularly true of Great Britain.

As well as carrying out industrial gerontological research (the science of ageing, *not* old age) in the British iron and steel industry and the Sheffield cutlery industry and social gerontological research in the homes of retired cutlery workers, I have been working on an investigation into community and individual reactions to population 'ageing'. The expectation of life at birth has almost doubled here in the past hundred years. This opens up great possibilities for individual and societal development. But, by and large, the complex problems involved have been handled along the lines of the past—with some quantitative improvements. Ideologically and organizationally, we are not equipped to cope with the present and impending situation.

Provision for Old People in Britain

Great Britain is well in advance of most countries in the provision of an almost universal national retirement pension, but this is comparatively low. In Sweden, the retirement pension for a single man is equivalent to some 25–30 per cent of an average working income and about 40 per cent for a married couple. This will shortly be based on the average of the fifteen best-paid years. In Federal Germany, the national retirement pension is linked with the cost of living². In Britain there is a universal National Health Scheme, which is of major benefit for older people, but there is still room for improvement in it; and, unlike France, Britain has no University Department of Geriatric Medicine. Again, in Britain the system of statutory and voluntary services for the old compares very favourably with that of most other countries; but it is still in its infancy and such services have a very limited coverage³.

Psycho-social and Industrial Gerontology in the United States

The three main divisions of research on ageing are: (a) biological; (b) clinical medical; (c) psycho-social and

industrial. The last-mentioned is a very recent development, but it is now widely agreed that it is of major importance to society.

One of the outstanding papers given at the 1963 Copenhagen Congress of the International Gerontological Association was that of Dr. Wilma Donahue, of the University of Michigan. She gave a factual report on "Organization of University Training for Teaching and Research in Psycho-Social Gerontology". It may be mentioned that the United States is demographically 'younger' than Great Britain. Dr. Donahue outlined the American academic situation. University departments of social and industrial gerontology and the like have been established in at least six American universities and fifteen special university units; there are three multi-university organizations for promoting such teaching and research and applied research; there are twenty-six departments of psychology and twenty-two departments of sociology paying special attention to social and industrial gerontology. Yet Dr. Donahue states that in this connexion: "Effort has been too limited and progress too slow".

In the United States there is a national Gerontological Society with a professional and lay membership of more than a thousand. The section concerned with social, psychological and industrial gerontology is one of the largest and most important of the three. In addition to this, a considerable number of the member States have their own gerontological societies. There is a great deal of publicity given to the subject of ageing in all its aspects in American newspapers, journals, books and sound radio and on television programmes. The Federal and State Governments and the private research foundations have made available quite large sums of money for research in all aspects of ageing.

Psycho-social and Industrial Gerontology in Great Britain

What are the comparative university and organizational provisions in Great Britain? I take my statistics from *Scientific Research in British Universities*⁴ and the *Register of Social Research on Old Age*⁵. No British university has a department for social, let alone industrial, gerontology. In all, in seven British universities, research workers are listed as working in some aspects of ageing; but this is chiefly with socio-medical surveys and the like. Less than one university research worker in a thousand in Great Britain is listed as engaged on any research project however remotely connected with ageing or old age. It would seem that all research workers in this field in Britain are self-trained; in the United States the university departments already mentioned have trained several hundreds. Within recent years more publicity has been given in Great Britain to the subject of ageing, but it has been chiefly along the lines of the 'care and comfort of the aged poor'. At long last a Social Science Research Council is to be formed in Great Britain; but no mention is made of its plans in connexion with research in social and industrial gerontology. Governmental and other

funds for research in this important field are extremely small in Great Britain.

Social and Industrial Gerontological Research Publications in the United States

One can refer to the *Classified Bibliography of Gerontology and Geriatrics*⁶. This lists the enormous amount of publication in all fields of research on ageing in the United States, and though this varies in quality, some of it is very good. A large bulk of it has to do with social and industrial gerontology. There are three major publications by the University of Chicago Press⁷⁻⁹. One could go so far as to say that the vast bulk of publication in this sphere comes from the American press, but unfortunately most of this is oriented to the American scene.

How Old is Old?

The population of England and Wales, as shown by the Census of 1961, gives us some statistics on those who could be classified as old in the community. If we take chronological age of sixty as 'old', this gives us 16.3 per cent. One person in six among us is old. But if we take it as fifty years and over, this gives us 31.8 per cent. Almost one person in three in the population of Britain can be described as 'old' by the age-typing commonly used on the factory floor. Again, let us take forty years and over. This gives us 45.4 per cent. The biologists tell us that physical later ageing commences as early as age thirty, and the psychologists that certain aspects of mental ageing are well established at age twenty. We do not know exactly what 'ageing' is; but for most people some pathological, physical or psychological concomitants of later ageing are present by age forty. On this reckoning, about half the population of Britain is old. This is based on the 1961 figures. In 1961 the largest five-year age-group was 10-14 years; the second largest 0-4, but the third largest was for people aged 35-39. In 1961, people between the ages of 35 and 54 could be considered 'middle-aged' (or shall we say in the 'prime of life'?). This twenty-year age grouping made up 27 per cent of the population of the period. It is a 'bulge' moving up the population age structure.

Gerophobia in contemporary Great Britain. There is considerable evidence that in Great Britain, indeed throughout the Western world, we suffer badly from gerophobia—which I have defined as a "morbid or pathological fear of late ageing". I have investigated this in the national Press as well as in my contacts in industry and society.

There is a connexion here with what the American social gerontologists call the 'role-less role' of many retired people in modern Western societies.

Emotional health from middle age; the quality of life at later years. The motto of the American Gerontological Society is: "To add life to years not years to life". A central problem is that of the psychological (mental emotional) well-being of not only older people, but also of people from middle years onwards. This relates with having some role and function in society and, indeed, in industry—where that is desired and possible. Recent publications in psychiatry and social psychiatry have emphasized this (ref. example, ref. 10).

Male Work-force 'Ageing' in the British Iron and Steel Industry and the Cutlery Industry

In Great Britain there is a middle-aged male work-force; more than 50 per cent of the men are aged forty years and more. But these average figures hide the considerable proportion of companies and departments where the male work-force is very much 'older'. I have investigated the age composition of the male work-force of the British iron and steel industry. A half-page report of this, entitled "Survey of the Age Structure of the British

Iron and Steel Industry", was published by the *Manchester Guardian* of November 5, 1957¹². It covered more than 145,000 workers in 96 companies of all sizes in six national areas with large sub-samples for the skilled divisions and for twelve major occupational divisions. A salient finding was the large proportion of departments and companies with considerable numbers of older men—those having from one in five to one in three of their men age fifty-five and over, and with relatively high proportions of other later age groupings. More recently, I carried out an age composition survey of the Sheffield cutlery industry. Some of the male work-forces there have extraordinarily high proportion of men at later years. A 1952 (ref. 11) sampling of the age composition of the Sheffield cutlery and associated products industries gives an indication of this (Table 1).

Table 1

Proportion of male workers in given age grouping (years)	Sample Sheffield cutlery and associated products 1952 (% of total)	Estimate for national male work-force (Ministry of Labour mid-1952) (% of total)
(i) 45 and over	56	38
(ii) 55 " "	34	17
(iii) 65 " "	16	4

Organizational and Institutional Necessities for Contemporary Great Britain

There appear to be four prime necessities if Britain is to take up this challenge of population 'ageing' (or is it 'maturing'?):

(1) A widely membered professional and lay British Gerontological Society, with a section for sociological, psychological and industrial gerontology as well as sections for biology and clinical medicine. In Great Britain there are a British Society for Research on Ageing (chiefly for biologists) and a British Geriatric Society (for the medical profession); but there is no comparable organization for the social sciences.

(2) At least one British University Department of Social and Industrial Gerontology—for pure research, applied research and university and extra-mural teaching. It will take some time to bring into being such a university department. But possibly Her Majesty's Government will help in this respect.

It is suggested that a number of Regius chairs of social and industrial gerontology be established in Britain in the coming quinquennium.

(3) A British Institute of Applied Gerontology, which would bring together concerned academics and leaders from both sides of industry and from the social services, etc.

(4) An Inter-Ministry Committee on Sociological, Psychological and Industrial Gerontology, to help, advise and guide the Government, the public and concerned bodies and to facilitate the acquisition of necessary funds for the furtherance of gerontological research and its application in all relevant aspects of this multi-disciplinary science and, particularly, in its sociological and industrial aspects.

In recent decades new faculties have been established in different universities in Britain, yet faculties of social science are still comparatively few in relation to the numbers of such in the United States; but even newer faculties are required for the universities of the twentieth century. The University of Chicago has established a Faculty (or is it only a Department?) of Human Development. This is a very good title because it enables us to see ageing in life perspective. It is to be hoped that in the coming decades a number of new departments, if not faculties, of this nature will be established in Great Britain.

The sixth congress of the International Gerontological Association is to be held in Vienna during June 26–July

2, 1966. It would be highly desirable if Great Britain could form a nucleus of a National Gerontological Society with this missing third section for a sociological, psychological and industrial gerontology. Great Britain seems to be one of the few modern States which has not brought about this organizational development. I should like to contact all those interested in the proposals. Research is important, applied research is even more important; but for us now yet more important is an appropriate national organization. My address is: 26 Dransfield Road, Sheffield 10.

It is hoped to convene a meeting shortly in Birmingham, as a central city, to discuss this more thoroughly and to bring such an organization into being. I should appreciate comments on this article, offers of support and, indeed, offers of funds; a start could be made with a few thousand pounds, and this should yield a considerable return to the nation. This has been a very brief sketch of the situation, but I appreciate that the whole matter must be discussed by people from different university disci-

plines, from industry and the Trade Unions, and from Government departments, etc.

OBITUARIES

Prof. R. Spärck

WHEN Ragnar Spärck died on June 20 at the age of sixty-eight his passing left a gap in many circles, created by his central position in Danish zoology, his wide intellectual interests and his extraordinary personality. Few men in his profession have filled so many posts and performed such various duties.

For a period of almost forty years Spärck taught zoology in the University of Copenhagen, from 1937 as professor, occupying the old tradition-rich chair of systematic zoology in the University. The general acknowledgment in Denmark of taxonomy as a necessary background for more recent trends in zoology is largely due to his education of a whole generation of zoologists. Among the students he was equally popular as an inspiring teacher and a cheerful mid-point during social events and on excursions. His elegant appearance as University opponent at public defences of more than fifty theses was widely appreciated, even by the candidates.

Already as a student, Spärck had acquired a position at the University Zoological Museum. In the early 'twenties he put forward a bold plan for a new museum building; but it was not until he became professor and head of the Museum Council that he could put authority behind his plans. The Second World War postponed the erection of new and badly needed quarters, but in 1960 the Students' Laboratory and Study Collection was finished and three years later the large staff and rich collections of the Museum moved into an adjacent, well-planned building. He also played an active part in the consequent erection of a third, now almost finished, spacious building for comparative anatomy and experimental zoology.

Spärck's contribution to science falls mainly within two fields, marine biology and history. As a pupil of C. G. Johs. Petersen, he carried on his investigations of bottom communities, mainly in areas outside of Denmark. He wrote his doctoral thesis on the biology of the European oyster and served for the rest of his life as an adviser for the oyster cultivation in the Limfjord. Only to a lesser extent did he join marine expeditions (for example, in the Mediterranean during the *Dana* Expedition, in East Greenland, and in South Africa during the *Galathea* Expedition). However, both before and after the War he was very active behind a long series of Danish expeditions to East Greenland, the Iranian Gulf, West Africa, and not least the *Galathea* Deep-Sea Expedition. He was vice-president of the *Galathea* Committee and acted as the co-ordinator on the 'home-front', an extremely

important but not widely recognized position during accomplishment of large expeditions.

During his later years Spärck devoted much of his energy to the history of natural sciences in Denmark. A profound interest in the work and conditions of the predecessors, an extraordinary memory for details and a superior view for general lines was the basis for his important authorship of books and papers on historical subjects, for example, on the Zoological Museum and zoology teaching during 300 years, on early Danish expeditions, on the Natural History Society, and on Japetus Steenstrup, the leading Danish zoologist of the last century, with whom Spärck had so much in common.

Spärck's work for nature conservancy was legendary. He was a member of the Conservancy Council for almost forty years, the last sixteen years serving as a chairman. He knew his native country as few others and had an ability to make odds and ends meet in the not always easy negotiations with authorities and proprietors. He was also a leading force behind the Danish game sanctuaries, and, thanks to his initiative, a long series of papers on game biology have been published.

Spärck was well known abroad. He liked travelling and as a result of his broad interests and attainments he attended congresses and meetings within many fields of zoology and marine biology, museum work, nature conservancy and zoological gardens. He was a member of the International Committee of Zoological Congresses and the president of the Copenhagen Congress in 1953. He was also for six years president of the zoological section of the International Union of Biological Sciences and was a member of several other international committees (for example, on Zoological Nomenclature, the Zoological Record and Nature Conservancy).

TORBEN WOLFF

Mr. K. E. B. Jay, M.B.E.

MR. K. E. B. JAY, who was well known for his popular books on atomic energy, died at his home in East Hendred, Berkshire, on August 3, at the age of fifty-five. Kenneth Edmund Brian Jay was the son of Joseph Jay, a company secretary, of Amersham. From 1923 until 1929 he was educated at University College School, London, and then went on to University College, where he read physics. After only a year, his studies were interrupted by a long and painful illness, leaving him with a serious physical disability, which remained for the rest of his life. Jay resumed his studies in 1935, and in 1938 he graduated

with first-class honours in physics, and was awarded the Granville scholarship. After taking his degree, he began research on electron diffraction under Prof. E. N. da C. Andrade, who was much impressed by his character and ability.

At the beginning of the Second World War, Jay joined the Air Ministry Telecommunications Research Establishment (later the Royal Radar Establishment). It was here that his abilities as a writer first came to notice, and after a short spell of experimental work he was attached to the chief superintendent, Mr. A. P. Rowe, to prepare the establishment progress report and other documents. Rowe attached great importance to presenting technical information to the layman in an intelligible form, and he would not tolerate jargon; his views undoubtedly left their mark on Jay's future career. When the Telecommunications Research Establishment moved to Malvern, Jay set up an information room, where all forms of graphical presentation were used to bring out the contribution of radar to the successful conduct of the War. During this period Jay did much to strengthen the chain of communication which was so successfully established between the scientists in the Telecommunications Research Establishment and the serving officers in the Royal Air Force.

In 1945 Jay went to the Cabinet Office to work on the *Official History of the War*. There he conducted the researches and composed the narrative relating to the history of radar, which was incorporated in the volume on the *Design and Development of Weapons*.

Three years later, Jay joined the Atomic Energy Research Establishment at Harwell as information officer, and in this post he laid the foundation of the present information service. However, he retained his interest in the more popular presentation of scientific information, and when the declassification of atomic information began to gather momentum in 1951, he put forward a proposal for a book on the work of the Atomic Energy Research Establishment. This was published in 1952 under the title *Harwell, the British Atomic Energy Research Establishment*; it was the first serious description of post-war nuclear research in the United Kingdom, and was an immediate success. This success led to Jay's transfer to a full-time, scientific-writing post, and in the next few years there followed four more books: *Britain's Atomic Factories* (1954), *Atomic Energy at Harwell* (1955), *Calder Hall* (1956) and *Nuclear Power Today and Tomorrow* (1961). Although the visits to distant establishments were a serious physical burden, he perhaps most enjoyed writing the books on the factories and Calder Hall, where an account of the scientific principles involved was combined with a fascinating story of engineering initiative and enterprise.

In addition to these major works, Jay was responsible for many years for writing the chapters dealing with research in the Atomic Energy Authority's annual report, and for a series of progress reports on activities at the Atomic Energy Research Establishment prepared for internal use in the Authority. He also wrote an introductory chapter to the first volume of Mrs. M. Gowing's official history of the United Kingdom atomic energy project, *Britain and Atomic Energy, 1935-45*.

In all his writing Jay took immense pains both to keep in mind the needs of his readers for a clear and simple exposition, and also to preserve scientific accuracy. In this way he was able to achieve the objectives he set himself, and at the same time to retain fully the confidence of the scientists about whose work he wrote: nearly all his writing was based on first-hand discussion with them.

A catalogue of his written work, however, cannot adequately represent the impact which Jay made on Harwell, and the Atomic Energy Authority. He was an excellent lecturer both in the history of atomic energy and on the presentation of scientific information; he was an active worker for standardization of nomenclature, and

was chairman of a British Standard Institution sub-committee which produced their *Glossary of Terms used in Nuclear Science*. But perhaps most important, in the face of physical adversity he showed a cheerfulness and determination which were an example to all, and with his warm personality, he inspired the affection as well as the professional admiration of all who knew him. His award of the M.B.E. in 1956 was universally acclaimed.

Outside his office, as at work, Jay did not allow his disability to limit his activities. He was chairman of the Atomic Energy Research Establishment's Amateur Radio Club, an active worker for his parish church, and a member of the Science Writers' Guild. He was also author of some illustrated children's books on science, including *British Nuclear Reactors* (1960).

Science is becoming more complex, more expensive and more difficult to understand; at the same time, its understanding by laymen in industry and Government must increase if science is to be efficiently applied. Kenneth Jay had an outstanding ability to bridge this gap in communication between scientists and laymen; there is a great need for many more like him.

R. M. FISHENDEN

Dr. Duncan A. MacInnes

DR. DUNCAN A. MACINNES, member emeritus of the Rockefeller University, died on September 23, in Hanover, New Hampshire. He was eighty years of age and had been active in scientific research until this past summer.

Dr. MacInnes had been affiliated with the Rockefeller University since 1926 and had been a member emeritus since 1950. During his career, he distinguished himself in teaching and research in several universities and as a civilian with the Office of Scientific Research and Development during the Second World War.

Many honours were conferred on Dr. MacInnes. He received the Nichols Medal in 1942, awarded by the American Chemical Society to stimulate original research. In 1948 he received the Acheson Medal, awarded every two years by the Electrochemical Society. He was also honoured with the Presidential Certificate of Merit in 1948.

Dr. MacInnes's field of research had been largely directed towards the study of electrolytes in aqueous solution. As emeritus member, he had continued to conduct laboratory research.

Born in Salt Lake City, Utah, March 31, 1885, he received his B.S. degree from the University of Utah in 1907. In 1909 he received his M.S. degree from the University of Illinois and his Ph.D. degree in physical chemistry in 1911. During the next six years he was successively an instructor and an associate in chemistry at the University of Illinois. During 1917-26 Dr. MacInnes carried out physical chemistry research at the Massachusetts Institute of Technology, first as an assistant and then as an associate professor. In 1926 he became an associate member of the Rockefeller Institute (now the Rockefeller University), in 1940 a member, and member emeritus in 1950.

He was a member of the National Academy of Sciences, the American Association for the Advancement of Science, the American Chemical Society, the Electrochemical Society (for which he served as president during 1935-37), the American Philosophical Society, and the Harvey Society.

✓ Prof. Hermann Staudinger

HERMANN STAUDINGER, whose death occurred on September 8, at the age of eighty-four, was a pioneer in the study of macromolecules and one of the founders of the subject of polymer chemistry. Born at Worms (Rhein) on March 23, 1881, he was educated at Halle, Darmstadt and Munich. In 1907 he became a lecturer in

chemistry at the University of Strasbourg, and after one year there he was appointed as an extra professor at Karlsruhe Technical High School (1908-12). After holding an ordinary professorship at the Federal Technical School, Zurich (1912-26), he was appointed to a professorship at Freiburg im Breisgau in 1926—a post which he held until he retired on reaching the age of seventy.

In his early years, Staudinger worked in the field of classical organic chemistry and with its well-defined substances which could be fully characterized by standard methods. The outcome of this work was the well-known monograph on *The Chemistry of the Ketenes*. It was not until the early 1920's that he selected as his field—at that time scarcely thought to be worth the consideration of an organic chemist of his reputation—the study of natural organic substances of high molecular weight. In this area he performed, with numerous collaborators, an enormous amount of experimental work on materials varying from natural materials, such as starch and cellulose, to synthetic substances, such as polystyrene and polyaldehydes, applying purely organic methods. He demonstrated that large linear molecules could be formed from small molecules by ordinary chemical reactions and, what is more, maintain their individuality even when they were subjected to chemical modification. Through this work he built up information for the foundation of the new branch of macromolecular chemistry. In one of his first publications he deplored the prevailing tendency to formulate polymeric substances as association compounds held together by "partial valencies" and he proposed the chain formulations of polystyrene and polyformaldehyde which are the ones accepted at the present time. He also advocated the long-chain structure of rubber and attributed the colloidal properties of these substances entirely to the size of their primary valence molecules. His chemical studies left no doubt as to the linear chain-like structures of these substances which he called 'macromolecules'.

In a paper published in 1926, Staudinger remarked that "many of the properties of synthetic high polymers are so similar to those of natural origin that they may be used as substitutes for them. It is not improbable that sooner or later a way will be discovered to prepare artificial fibres from synthetic high molecular-weight products because the strength and elasticity of natural fibres depend exclusively on their macromolecular structure". How brilliantly this prediction was fulfilled in his lifetime is commonplace knowledge. Staudinger's views were not

widely accepted at once. Many of his colleagues in high academic positions remained for a long time unconvinced. They did not approve either of his methods and results or the manner in which he elevated his own working field to a "new branch of organic chemistry". Many will recall the numerous occasions in the 1920's and early 1930's when the history of polymer science was made in the eloquent clashes between Staudinger—who relentlessly championed the macromolecular hypothesis—and those who believed that polymers were aggregates of small molecules. One of his best-known contributions was the establishment of a relationship between the viscosity of a solution of a high polymer and its molecular weight. As with other aspects of his work, much doubt and controversy centred on the so-called viscosity law which Staudinger proposed in 1930. The difficulties, however, were soon resolved, and the utility of the later modified relationship between viscosity and molecular weight played an important part in the determination of molecular weights and in the development of the physical chemistry of high polymers.

Staudinger's importance in the development of polymer chemistry is now universally accepted. His prodigious output of research and publications and his never-failing enthusiasm in a field in which he had to fight at every step to establish new concepts or justify new methods places him first when it comes to the question of who contributed the greatest number of facts and figures to the new macromolecular chemistry.

In addition to his outstanding scientific achievements, Staudinger was also a great teacher, who succeeded in transmitting his new ideas and creative thinking to the very large number of students always working in his laboratory. These students carried with them into academic life and industry the convictions of their master, and a generation of leaders in polymer science emerged.

Staudinger's many honours included the Nobel Prize for Chemistry in 1953; honorary degrees of Karlsruhe (1950), Mainz (1951), Salamanca (1954), Zurich (1955) and Strasbourg (1959); and honorary membership of numerous academies of science and scientific societies. He was awarded the Leblanc Medal of the French Chemical Society (1931), Cannizzaro Prize, Rome (1933), and Goldene Ehren-Medaille des Vereens der Textil-chemiker (1962). He was made an honorary citizen of Freiburg in 1955.

C. E. H. BAWN

NEWS and VIEWS

Royal Society of Edinburgh: Elections

At the annual statutory meeting of the Royal Society of Edinburgh, held on October 25, the following were elected to the Council of the Society for the 183rd session: *President*, Prof. J. N. Davidson; *Vice-Presidents*, Prof. C. F. Davidson, Dr. M. Ritchie, Prof. J. Allen, Dr. G. H. Mitchell, Prof. A. E. Ritchie, Prof. C. H. Waddington; *General Secretary*, Prof. N. Feather; *Secretaries to Ordinary Meetings*, Dr. A. F. Brown, Prof. W. L. Weipers; *Treasurer*, Dr. J. R. Peddie; *Curator of Library and Museum*, Dr. R. Schlapp; *Councillors*, The Right Hon. Lord Balerno of Currie, Dr. J. M. Jackson, Prof. I. N. Sneddon, Prof. P. E. Weatherley, Dr. Neil Campbell, Prof. P. L. Pauson, Prof. J. R. Raeburn, Prof. J. D. Robertson, Prof. P. W. Brian, Dr. H. E. Butler, Sir David Lowe, Dr. D. G. Sopwith.

Metallurgy in the University of Oxford:

Prof. W. Hume-Rothery, O.B.E., F.R.S.

PROF. W. HUME-ROTHERY will retire from the Isaac Wolfson chair of metallurgy in the University of Oxford

on September 30, 1966. His long and distinguished scientific career has been spent almost entirely in Oxford, and the date will be a sad occasion for his friends and colleagues. Prof. Hume-Rothery intended to make his career in the Army (and would surely have become a general!), but a serious illness as a young man left him totally deaf, and he turned to science instead. After taking an Oxford first in chemistry, he worked for his Ph.D. at the Royal School of Mines, and then returned to work in Oxford in 1926. Using his chemical background to great advantage, he began there the work on the theory of alloy formation for which he is so renowned, and the Oxford school of alloy chemistry eventually grew into the present Department of Metallurgy. In 1957 he became the first professor of metallurgy in Oxford, and the choice was so unquestionable that the University dispensed with the formality of an election. Throughout his career, "H. R." has played a leading part in associating metallurgy with solid-state physics and chemistry. He pioneered the scientific approach to metallurgy, not only by his own research, but also by his brilliant expositions of basic theory in books which

have been used by generations of students and which have been translated into many languages. His early work was accomplished with slender resources in cramped accommodation, but led to widely acclaimed generalizations such as the size factor rule and the existence of electron compounds. He was elected a Fellow of the Royal Society in 1937, and has received awards and honours from scientific societies in Britain, the United States, The Netherlands and Italy, including the Platinum Medal of the Institute of Metals in 1949.

Metallurgy at Oxford has always been associated with the name of Hume-Rothery, and without his enthusiasm it would never have attained the status of an independent Final Honour School. His interests in teaching no less than in research have been fully engaged since the Second World War, and he hands on to his successor a Department which already enjoys a high reputation. All will wish "H. R." a long and happy retirement, but it will be surprising if he does not immediately begin work on another book.

Prof. P. B. Hirsch, F.R.S.

DR. P. B. HIRSCH, reader in physics at the Cavendish Laboratory, Cambridge, has been elected to the Isaac Wolfson professorship of metallurgy in the University of Oxford, as from October 1, 1966, in succession to Prof. W. Hume-Rothery. He was born in 1925, and graduated at Cambridge in 1946, with a first-class honours degree in physics. He then joined the late J. N. Kellar as a research student in the Cavendish Laboratory, and together they developed an X-ray microbeam technique for the study of the microstructure of deformed metals, under the direction of Dr. W. H. Taylor. In 1950, Dr. Hirsch initiated at the Cavendish Laboratory, on behalf of the National Coal Board, an X-ray diffraction study of the structure of coals and of the carbonization process. From about 1955 onwards he turned his attention again to problems in plasticity, work-hardening and defects in metals. He was responsible for developing, with Dr. M. J. Whelan, the electron microscope transmission technique for the study of defects in crystals. This work led in 1956 to the first direct observations of the movement of dislocations in metal foils. During the next few years Dr. Hirsch and his colleagues developed the experimental techniques and theories of image contrast which make it possible to determine from electron micrographs the detailed nature of defects. During this period the collaboration of Hirsch, Howie and Whelan was particularly successful. The technique was also applied to a number of problems, including dislocation interactions, defects in quenched and irradiated metals, dislocation distributions in metal crystals deformed in tension and fatigue, and recrystallization. This work was a major and fruitful advance in metal physics and it established the electron transmission microscope technique as a powerful tool in metallurgy. Dr. Hirsch also made outstanding contributions to the theory of dislocations and work hardening. It is recognized internationally that the group which has grown around him in the Cavendish is a leading one in the field of metal physics. Dr. Hirsch was elected a Fellow of Christ's College, Cambridge, in 1960, a Fellow of the Royal Society in 1963, and was awarded the Rosenhain Medal of the Institute of Metals in 1961, and the C. V. Boys Prize of the Institute of Physics and the Physical Society in 1962. When he takes up his new appointment he will be responsible for the proposed expansion of metallurgy at Oxford and for broadening the interests of the Department towards materials science.

Geography in the University of Reading :

Prof. A. Austin Miller

PROF. A. AUSTIN MILLER retired from the chair of geography in the University of Reading on September 30 after nearly forty years in the Department of Geography there. A graduate in geology of University College,

London (B.Sc. first-class honours 1922, M.Sc. 1925, D.Sc. 1940), he was appointed lecturer in geography at Reading in 1926 and professor of geography in 1943. His work has dealt mainly with the physical aspects of geography and in 1931 he established an international reputation for himself with the publication of *Climatology* which, with due revision through nine editions and several translations, remains a standard text-book in 1965. In addition to many papers, his publications also include *The Skin of the Earth* (1953) and (with M. Parry) *Everyday Meteorology* (1958). For his work in geomorphology and climatology he received the Murchison Award of the Royal Geographical Society in 1963. A founder-member of the Institute of British Geographers, he became in due course its youngest president in 1946-48, and later was president of Section E of the British Association for the Advancement of Science (1956) and of the Geographical Association (1963). He has served on the Council of the Royal Geographical Society and was advisory editor on geography to the new *Chambers' Encyclopaedia*, 1945-49. In 1958 he was elected Fellow of University College, London, the same year in which he was visiting professor at the Universities of Indiana and British Columbia. He also held offices at meetings of the International Geographical Union at Lisbon 1949, Washington 1952, Rio de Janeiro 1956, and Stockholm 1960.

Prof. T. G. Miller

MR. T. G. MILLER, who has just taken over the chair of geography at the University of Reading from Prof. A. Austin Miller, is a geologist by training. Demobilized after the Second World War with the rank of major, he then graduated in geology at Cambridge and was appointed University demonstrator in geology and Fellow of Jesus College, a post that he occupied until 1953, when he transferred to the University College of North Staffordshire (now University of Keele). Prof. Miller's interests have been in the realms of physical geography—exemplified in his *Geology and Scenery of Great Britain*—in Carboniferous palaeontology and in stratigraphy; while in the Territorial Army he has been concerned with terrain studies from a military point of view. He thus continues at Reading the wide interest in the physical aspects of geography that Prof. Austin Miller has cultivated for almost forty years.

Assistant Chief of the National Bureau of Standards Textile and Apparel Technology Center :

Dr. F. C. Brenner

DR. F. CECIL BRENNER has been appointed assistant chief of the Textile and Apparel Technology Center of the National Bureau of Standards Institute for Applied Technology. He will be responsible for developing new research projects and managing existing ones. The programme of research of the Textile and Apparel Center is designed specifically to meet the needs of industry. Dr. Brenner will maintain close contact with technical and trade associations and educational institutions as well as with industry, enabling him to carry on research useful to the industry. He is particularly well qualified for his new position as he has conducted research on fabric properties for end-use performance. He has also investigated the effect of textile finishing processes on the mechanical behaviour of fabrics which determines their stiffness, drape and wrinkling performance. Recently, Dr. Brenner was a member of the Chemstrand Research Center in Durham, North Carolina, and earlier of Johnson and Johnson Co. He gained his Ph.D. degree in polymer chemistry at the Polytechnic Institute of Brooklyn, and was appointed an instructor at the Institute, and later an assistant professor of physical chemistry at Vanderbilt University. Dr. Brenner is a member of the American Chemical Society, Fiber Society, Inc., and the American Association of Textile Chemists and Colorists.

Social Science Research Council

IN a written answer in the House of Commons on November 2, Mr. A. Crosland, Secretary of State for Education and Science, stated that further to the appointment of Dr. M. Young as chairman of the Social Science Research Council, the following members of the Council had also been appointed: W. O. C. Adamson, A. L. C. Bullock, Prof. J. Drever, Prof. R. W. Firth, Sir William O. Hart, Prof. Marie Jahoda, Lord James of Rusholme, Prof. R. G. Lipsey, Prof. W. J. M. Mackenzie, Prof. T. H. Marshall, Prof. C. A. Moser, L. Murray, Prof. R. M. Titmuss and G. D. N. Worswick. A draft of the Charter to be granted to the Council has been approved by Her Majesty in Council, and a draft Order specifying the objects of the new body and declaring it to be a Research Council for purposes of the Science and Technology Act, 1965, has been laid before Parliament.

Desalination of Sea-water

IN a written answer in the House of Commons on October 27, Mr. F. Cousins, the Minister of Technology, stated that the Atomic Energy Authority and industry had completed a design for a plant to produce 30 million gallons of fresh water a day from sea-water. Further design work had been done, particularly in respect of dual-purpose plants for producing electric power and fresh water from nuclear reactors, and economic studies on these plants had been made in some detail. The great contribution already made by Britain had been recognized at the recent international conference on desalination in Washington. More than two-thirds of all land-based desalination capacity in the world, including the biggest sea-water distillation plant at Kuwait, with a capacity of 1.4 million gallons a day, was built by British industry. Much interest was also shown at the Washington conference in Britain's design studies for combined power and distillation plants. In conjunction with Weir Westgarth and the nuclear engineering industry, the Authority had done much to improve the steam cycle of these dual-purpose plants. The flash-distillation process remained the most promising process so far available, and every effort was being made to improve its technical and economic efficiency. Work had also been started on alternative processes, such as reverse osmosis and electrodialysis, which might become increasingly important.

Research and Development in the Building and Civil Engineering Industries

IN a written answer in the House of Commons on November 1, Mr. C. Pannell, the Minister of Public Building and Works, stated that during the past 9 months the Directorate General of Research and Development had made a comprehensive review of research and development related to the building and civil engineering industries. It had commissioned from universities some research projects relevant to the construction industry and was studying proposals for increasing the resources available for building research and the dissemination of technical information in the industry. Design work had started on a £1 million pre-production programme for the Department's steel-framed system, Nenk. Further progress had been made with dimensional co-ordination and a start had been made on the change to the metric system. The Department had continued its work on winter building and had issued a film on techniques suitable for smaller builders. It continued to collect, analyse and disseminate statistical information, and to advise on the construction industries in connexion with the Government's economic planning. The Ministry was represented on the Economic Development Committees for the civil engineering and building industries by members of the Directorate.

Solway Firth Barrage

IN answer to a question in the House of Commons on November 3, Mr. W. Ross, the Secretary of State for Scotland, said that, as a result of the moratorium on capital expenditure announced in July, it was not possible to proceed immediately with the full-scale feasibility study of the Solway Firth Barrage. However, arrangements had been made for Messrs. Babbie, Shaw and Morton to start a preliminary study, costing some £10,000-£15,000, on the quantity and quality of water that would be made available by a barrage.

Second Conference on the Countryside in 1970

WHEN the Duke of Edinburgh inspected National Nature Week in May 1963, what impressed him most was that so much goodwill and so many bodies interested in the care of the countryside were meeting with so little success in saving it. This he attributed to a lack of thorough enquiry and clear thinking which might enable all concerned to work in harmony and produce early and worth-while results. At his initiation, a study conference with that object was convened. It was felt that the countryside was in grave danger of irreparable damage by 1970. The first study conference in November 1963 brought the parties together, obtained fairly widespread agreement and helped towards resolving certain special problems such as the misuse of toxic chemicals on the land (*Nature*, 201, 958; 1964). It could not, however, tackle many deeper and more complex problems which needed more time and manpower.

This task has now been undertaken by twelve study groups and a number of other combined operations, and the results came before the second study conference opened by the Duke of Edinburgh on November 10 at the Royal Society of Arts. That day and the next were devoted to intensive examination by those responsible for preparing the conference documents with the view of bringing them together as a whole and defining ways and means of obtaining positive action. At this stage, Lord Strang, chairman of the National Parks Commission, and Lord Robens, chairman of the National Coal Board, took the chair in turn. On November 12 the final reports went to a larger plenary meeting at Fishmongers' Hall, at which Mr. F. Willey, the Minister of Land and Natural Resources, made a policy statement on behalf of the Government. Spokesmen of other national interests included Mr. John Davies for the Confederation of British Industries, Prof. C. Buchanan on "Road Use in the Countryside", Mr. Jack Longland on education, Mr. W. Deedes on "Information", and Mrs. G. L. S. Pike of the National Federation of Women's Institutes, speaking from the point of view of the country dweller.

The conference was sponsored by the Royal Society of Arts, the Nature Conservancy and the Council for Nature.

Central Building Research Institute, Roorkee, India

IT is always a matter of interest to students of building technology to learn, if only for comparative purposes, of the progress of research and of various lines of enquiry pursued in this field by organizations similar to the British Building Research Station, which have been established in other countries. India is no exception to this, as is clear from the annual report of the Central Building Research Institute, 1964-65 (India: Council of Scientific and Industrial Research. Pp. ix + 83. Roorkee (U.P.): Central Building Research Institute, 1965). In his foreword, G. Pande, chairman of the Executive Council of the Central Building Research Institute, makes these points: "... the trend of research in the Institute has been project oriented and greater emphasis has been given during the year on projects which have immediate impact on the building industry by way of increasing

productivity and reducing costs, with the maximum utilization of indigenous materials and improved techniques. . . . The Institute has also made good progress in the field of international co-operation, particularly in the exchange of research programmes and research results which will help in improving the quality of research work here". Some idea of the scope of the work of the Institute is conveyed by the titles of the sections into which this report is divided: building materials; soil engineering; structural engineering; efficiency of buildings; building processes, plant and productivity; architecture; information and survey; extension; and administration. In the introduction to the report, the director of the Institute, Dinesh Mohan, mentions several items of importance as affecting the progress of its work during the year under review; among these are: the installation of an IBM digital computer and the starting of a Computing Centre; an extension service, the opening of small liaison cells in other parts of the country, a start being made at Calcutta and Bhopal; the new laboratories of the Efficiency of Buildings Division; the difficulty of recruiting staff for vacant scientific posts, especially in the engineering disciplines, which has hampered progress in a number of research projects; and the popularity of the *Building Digests* issued by the Institute at regular monthly intervals. The Central Building Research Institute has now completed twelve years of its existence in the service of the building industry, and its close ties with international organizations, through the International Council of Building Research and Documentation, will ensure that its work in future will proceed, as in the past, on most progressive lines.

Chemical Industries Association, Ltd.

In 1964, the Association of British Chemical Manufacturers and the Association of Chemical and Allied Employers decided that it was vital, in view of the increased involvement of Government, irrespective of party, in industrial affairs, that their two organizations should merge to form a new and more powerful body. This merger has now been successfully concluded with the formation of the Chemical Industries Association, Ltd., which formally comes into being on January 1, 1966. The officers of the new Association will be: *President*, P. C. Allen; *Vice-Presidents*, Lord Netherthorpe and F. L. Waring; *Director General*, J. C. McEntee; *Director of Trade Affairs*, H. W. Vallender; *Director of Industrial Relations*, J. T. Collins; and *General Secretary*, A. J. Chant. Further information can be obtained from the Association of British Chemical Manufacturers, Cecil Chambers, 86 Strand, London, W.C.2.

Food Poisoning

Food poisoning, the subject of a symposium in *The Practitioner*, is a problem of unknown extent (195, No. 1165; July 1965). As Dr. G. E. Breen points out in the opening article, "it is probable that the condition is very much under-reported", and, in his opinion, unreported cases may amount to nearly 50 per cent of the overall incidence. In noting that there were 3,919 cases of human salmonellosis proved in England and Wales in 1963, Dr. J. Taylor comments that "this figure is probably about one-third of the actual number, as so many cases are not notified". In the United States it has been estimated that there are 2 million cases of salmonellosis every year, but whatever the precise figures, the incidence is much too large and leads to a great deal of personal inconvenience and loss of working time. Much of it could be prevented if only housewives, shopkeepers and restaurant keepers would observe certain simple rules of hygiene; however, while prevention is the ideal way of tackling the problem, there will always be a modicum of cases, no matter how efficient preventive measures may

be. It is in the detection of these that the general practitioner occupies the key position. The ultimate responsibility for coping with any 'incident' rests on the medical officer of health, but he is obviously at a disadvantage unless he is notified of a case at the earliest possible moment by the family doctor. The symposium has been prepared in order to provide an up-to-date, authoritative account of what can be done to control this unnecessary incidence of disease.

Care of Laboratory Animals

PUBLICATIONS Nos. 1284 and 1285, issued by the National Research Council of the National Academy of Sciences, 2101 Constitution Avenue, Washington, D.C., will interest all who are concerned with the maintenance of laboratory animals and their use in experimental work (No. 1284: *Laboratory Animals: Animal Medicine*. Pp. vii + 35. 1.25 dollars. No. 1285: *Laboratory Animals: Training*. Pp. v + 57. 1.50 dollars. Washington, D.C.: National Academy of Sciences-National Research Council, 1965). They outline the plans put forward by the Institute of Laboratory Animal Resources for graduate training in laboratory animal medicine. College programmes now providing this training are examined. For this purpose, eighteen veterinary schools have been visited. Other publications in the series on *Laboratory Animals* are entitled: *The Shipment of Laboratory Animals* (1.50 dollars); *A Directory of Sources of Laboratory Animals, Equipment and Service* (2.00 dollars); *Recommended Minimum Standards for the Shipment of Laboratory Primates* (1.50 dollars). These publications express the welcome recognition in the United States of the fact, long recognized in Britain, that animal care is a profession and a discipline, and that those who look after laboratory animals should be fully trained for their work. They need to understand the biology of the animals under their care, their sanitation, hygiene, housing, shipment and the equipment needed for this. Furthermore, they should be able to ensure their safety and deal with such matters as administration, management and the keeping of records.

Veterinary Non-proprietary Names

THE British Veterinary Codex Revision Committee has adopted the following non-proprietary names for the veterinary substances indicated:

Non-proprietary name	Other names
Oxyclozanide	3,5,6,3',5'-pentachloro-2,2'-dihydroxybenzanilide; I.C.I. 46,638.
Pyrimithate	2-dimethylamino-6-methylpyrimid-4-yl diethyl phosphorothionate; I.C.I. 29,661.
Tetramisole	2,3,5,6-tetrahydro-6-phenylimidazo-[2,1-b]thiazole; I.C.I. 50,627

The non-proprietary names are reported to be free from conflict with trade marks registered in Great Britain and Northern Ireland, and these names, or names resembling these names, will not be registered as trade marks for pharmaceutical products or drugs in those countries. Some of the names, other than the chemical names, appearing in the second column here are registered trade marks. The adoption of a non-proprietary name does not necessarily imply that the British Veterinary Codex Revision Committee recommends the use of the substance in veterinary medicine or that the substance will be included in the *British Veterinary Codex*, although if a substance is included, it is intended that the non-proprietary name shall be the title of the monograph. The British Veterinary Codex Revision Committee has undertaken, at the request of the Association of the British Pharmaceutical Industry, to provide non-proprietary names for veterinary products, and all requests from manufacturers and other interested persons for the provision of such names should be addressed to the Secretary, British Veterinary Codex Revision Committee, Pharmaceutical Society of Great Britain, 17 Bloomsbury Square, London, W.C.1.

Mitral Valve Disease

A SYMPOSIUM on advances in diagnosis and treatment of mitral valve disease was held at a regular meeting of the Section of Biological and Medical Sciences at the New York Academy of Sciences on October 14, 1963 (*Ann. N.Y. Acad. Sci.*, 118, Article 10: *Mitral Valve Disease*, by J. D. Baker and 11 other authors. Pp. 469-536. New York: New York Academy of Sciences, 1965). The moderator was G. H. Humphreys, who summed up the symposium as follows: "Disease of the mitral valve, usually of rheumatic but occasionally congenital origin, continues to be a major cause of disability in human beings in most countries of the world. It is interesting that the same valve is a frequent cause of heart failure in dogs, though the etiology appears to be different. It is of importance, therefore, that the search for better understanding of the pathological physiology, and improved diagnostic methods often based on, and sometimes adding to, this understanding be continuously pursued. At the same time, methods of more effective surgical correction of the valve are now available, so the criteria for selection of patients and choice of procedure must constantly be refined. It is evident from the papers presented in the symposium that much remains to be done in this field. If the experience in animal hospitals can be correlated with that in human, it is possible that new avenues of investigation may be opened".

The Association of Clinical Biochemists

THE following have been elected officers of the Association of Clinical Biochemists for 1965-66: *President*, Prof. R. H. S. Thompson (Courtauld Institute of Biochemistry, London); *Chairman*, Dr. R. Gaddie (General Hospital, Birmingham); *Secretary*, Dr. A. H. Gowenlock (Chemical Pathology Department, University of Manchester); *Treasurer*, Dr. D. B. Horn (Royal Victoria Infirmary, Newcastle upon Tyne).

Bullard Forest Research Fellowships

APPLICATIONS are invited for research fellowships in forest resources which are awarded annually by Harvard University from the Charles Bullard Fund. Such fellowships are tenable for one year and carry stipends up to 15,000 dollars. They are open to men in public service, in academic careers and in private forestry, with or without advanced degrees, who show promise of important contributions to forestry, which study and research at Harvard University will help to fulfil. Further information can be obtained from the Committee on the Charles Bullard Fund for Forest Research, Littauer Center 119, Harvard University, Cambridge, Massachusetts.

Guinness Awards for Science and Mathematics Teachers

THE Guinness Awards for Science and Mathematics Teachers are now to be extended so as to include Africa. This extension follows experience of the first results in the Guinness Awards programme in Ghana during 1964. The Awards scheme will now include the whole of English-speaking Africa. It is to be carried out in association with the Afro-Anglo-American conference financed by the Carnegie Corporation. Money prizes totalling £350 and certificates will be awarded. The purpose is to encourage teachers in schools and colleges in Africa to develop and report on the teaching of science in Africa with special reference to adaptations related to the African environment. The scheme for Africa will go into operation immediately and the first Awards are expected to be announced in April 1967.

The Guinness Awards for Science and Mathematics Teachers are also to be extended so as to include all schools run overseas by the Armed Forces. The three Services have agreed to collaborate, and the Royal Air Force

Educational Organization is to act as the co-ordinating centre. The first Awards will be announced in April 1967. Also to encourage mathematics, it has been agreed that financial and administrative aid shall be provided for the following two schemes: first, a National Mathematics Contest, now in its third year, in which the entrants are students in secondary schools, mainly grammar and public schools (in 1965 there were 5,000 entrants from 109 schools in the United Kingdom for this contest); secondly, the Mathematics Olympiad, organized by Prof. W. K. Hayman, of the Department of Mathematics, Imperial College of Science and Technology, and Mrs. Hayman, a mathematics teacher at Mayfield School, London. This scheme began in 1966. The first Awards under the auspices of the Guinness Awards for the National Mathematics Contest and for the Mathematics Olympiad are to be made in April 1966. As a result of the extensions to the Guinness Awards outlined here, the total value of prize money to be awarded annually will now be £1,500. Further information can be obtained from Mr. Maurice Goldsmith, c/o *The Science Teacher*, 60 Paddington Street, London, W.1.

Announcements

MR. W. T. COOPER, research editor of the Division of Coal Research, Commonwealth Scientific and Industrial Research Organization, has been appointed to succeed Prof. N. Y. Kirov as chairman of the Institute of Fuel (Australian Membership).

A MEETING of the Welsh Soils Discussion Group on "The Fauna and Flora of the Soil" will be held in the University College of North Wales, Bangor, on November 24. Further information can be obtained from C. C. Rudeforth, Soil Survey, Trawscoed, near Aberystwyth, Cardiganshire.

AN ordinary meeting of the Scottish Section of the Society for Analytical Chemistry will be held in the University of Strathclyde on November 26. A paper on "Separate or Calculate" will be presented by Dr. A. L. Glenn. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

A LECTURE on "The Reliability of Electronic Systems" will be delivered by Dr. Irving Bosinoff (Mitre Corporation, Bedford, Massachusetts) at the Institution of Electrical Engineers on December 3. Further information can be obtained from Dr. G. S. Brayshaw, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

A JOINT meeting of the Scottish Section of the Society for Analytical Chemistry and the local sections of the Chemical Society, the Royal Institute of Chemistry and the Society of Chemical Industry will be held in the University of Strathclyde on December 3. A paper on "Chemistry for Profit" will be presented by Dr. J. W. Barrett. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

THE 1966 Gordon Research Conferences will be held in Santa Barbara, California, during January 24-February 4. The purpose of the Conferences is to stimulate research in universities, research foundations and industrial laboratories and is achieved by an informal type of meeting consisting of scheduled lectures and discussion groups. The programme will include conferences on: polymers (January 24-28); chemistry of ageing (January 24-28); electrochemistry (January 31-February 4); formulation of research policies (January 31-February 4). Further information can be obtained from W. George Parks, Department of Chemistry, University of Rhode Island, Kingston, Rhode Island.

MEETING OF BIOCHEMISTS IN SPAIN

DURING July 28–31 the third general meeting of Spanish biochemists was held at the University of Oviedo, organized by the Spanish Society of Biochemistry and sponsored by the Ministry of Education and the University of Oviedo. The Minister of Education, Prof. M. Lora Tamayo, himself a biochemist, was the honorary president of the meeting.

At the opening session, Dr. A. Sols and Dr. J. R. Villanueva, president and secretary, respectively, of the Spanish Society of Biochemistry, gave a short historical review of the Society including its progress as shown through the programme of these meetings and other activities. Prof. F. Grande Covian, of the University of Minnesota, spoke in representation of the scientists coming from abroad, and finally the acting rector of the University expressed his pleasure at being with the Spanish biochemists.

The meeting centred about three symposia: (a) "Enzymatic Regulation"; (b) "Microbial Metabolism"; (c) "Hormonal Metabolism". The first symposium held was under the chairmanship of Prof. S. Grisolia, of the University of Kansas, and Dr. Gertrudis de la Fuente (Madrid) described the work on the allosteric effects in hexokinases, followed by M. L. Salas, who discussed the allosteric regulation of the yeast phosphofructokinase. C. Gancedo (Madrid) described some results on the allosteric yeast fructose-1,6-diphosphatase and the regulation of gluconeogenesis. Dr. Gertrudis de Torrontegui (Madrid) described the level of pyruvate carboxylase and related enzymes in micro-organisms grown on different carbon sources. Prof. S. Grisolia presented the work carried out in collaboration with Dr. Torralba and J. Tecson at the University of Kansas on the reversible transformation of phosphoglyceromutase in diphosphoglycerate phosphatase. J. Salas (Madrid) described results of the stability and synthesis of the liver glucokinase *in vitro* and *in vivo*. Finally, A. Sillero described the induction and turnover of the glucokinase in liver. The session was followed by a general discussion, and at the end Drs. A. Sols and S. Grisolia summed up the more important points of the symposium. This session was followed by a lecture by Prof. J. Oró, University of Houston, on recent researches on hydrocarbons of biological origin found in Pre-Cambrian sediments and meteorites.

In the second symposium, under the chairmanship of Dr. C. Asensio (Madrid), Dr. D. Vázquez (Cambridge) described investigations of the effect of some antibiotics inhibiting the synthesis of proteins at the ribosomal level. Prof. R. Parés (Barcelona) described work on amino-acid excretion by a coliform. Dr. E. Muñoz (Liège) described recent work carried out in collaboration with Drs. Ghuyssen and Petit on the structure of glucopeptides of the bacterial cell wall. Dr. Concepción García Mendoza (Madrid) described the purification and chemical analysis of the cytoplasmic membrane of yeast, and finally Dr. J. R. Villanueva (Madrid) reviewed the ways in which information about yeast cell wall structure

has been obtained and described some results obtained by his group at the Institute for Cell Biology. At the end of this symposium a discussion on "Unity and Variety in Microbial Biochemistry" was held, the main discussants being Drs. Losada, Mayor, Montoya, Parés, Regueiro, Sols and Villanueva. The session was followed by an address by Dr. M. Losada, director of the Institute for Cell Biology, CSIC, Madrid, who described the mechanism of the photosynthetic reduction of nitrate to ammonium.

In introducing the third symposium, Prof. F. G. Valdecasas, rector of the University of Barcelona, made some comments on the importance of the subject of hormonal metabolism. Dr. J. Gómez Acebo (Madrid) showed a collection of electron micrographs of pancreas cells during the process of insulin secretion *in vitro*. Dr. C. López Quijada (Madrid) reported the effects of iodoacetate and cysteine on the antigenic power of insulin. Prof. C. Osorio (Granada) described the process of secretion of thyroxine in bile of monkeys. Dr. J. A. Sanchez-Martin (Madrid) discussed the action of thyrotrophic hormone on the intra-thyroid metabolism of the propylthiouracil. Dr. E. Herrera (Madrid) discussed the problem of experimental goitrogenesis, Dr. A. Colás (University of Oregon) described the biosynthesis of the oestriol during pregnancy, and finally Dr. A. Oriol-Bosch (Madrid) described the metabolism of tritiated progesterone by the adrenal cortex of the guinea-pig. The session ended with an address by Prof. J. L. Rodríguez Candela, director of the Marañón Institute, CSIC, Madrid, who described investigations of his group and discussed the regulation of the insulin secretion. The symposia were followed by sessions where short communications were read. In all, about forty papers were presented.

During the closing session of the meeting, Prof. F. Grande Covian gave a lecture on the role of the dietetic factors in the regulation of the plasma lipids.

Several social events were also organized, including receptions in the University and the Town Hall, and an excursion to the beautiful resorts of the Asturias coast. Nearly two hundred people attended this meeting, including a notable group of Spanish research workers from abroad and many young research students. The meeting was very successful, especially in encouraging the strong development of biochemistry in Spain, which has been proceeding during the past five years. The next general meeting of the Society will be held in the University of Granada in the autumn of 1966.

The whole of the Oviedo University meeting made an important contribution to the way in which science, and in particular biochemistry, is growing in Spain. The progress has been strongly stimulated by the marked interest taken in biochemistry by some distinguished professors and research workers from the Consejo Superior de Investigaciones Científicas and the University. Recently, increasing attention has been directed in Spain to the means of developing scientific policy and the mechanisms of scientific advice.

J. R. VILLANUEVA

LUNG TUMOURS IN ANIMALS

AN international conference on "Lung Tumours in Animals" was held at the Division of Cancer Research, University of Perugia Medical School, during June 24–29. The conference brought together many geneticists, physiologists, pathologists, virologists and biochemists, whose main interests lay in basic cancer research.

Following the opening of the conference by Prof. G. Ermini (Rettore Magnifico of Perugia University), L. C. Strong (San Diego, U.S.A.), addressing the audience as the representative of the doctors 'honoris causa' of the

University of Perugia Medical School, said that the contributions of that small select group of scientists to the human knowledge of cancer had indeed been great—and that no small part of these contributions had been made, and would presently be made, at the Conferences of the Division of Cancer Research, Perugia.

H. L. Stewart (Bethesda, U.S.A.), speaking as the representative of the National Cancer Institute, Bethesda, commented that the conference should contribute much to our knowledge of the comparative pathology of pulmon-

ary tumours and help to decipher some of the puzzles that remain obscure about cancer of the lung in human beings.

Prof. L. Severi, in an introductory talk, commented that, because of the apparent increase in human lung cancer attributed to atmospheric pollutants and, on the basis of statistical investigations, especially to smoke, the conference was most timely. He pointed out, however, that lung cancer occurs in animals, which do not smoke, and that no conclusive evidence was available to show that tumours could be induced in them either with smoke or with the products of tobacco.

Lectures were given at the conference to emphasize important aspects of pulmonary carcinogenesis in animals as a whole, and a number of papers were presented. Of special interest was the brief address of Prof. W. I. B. Beveridge on the World Health Organization's programme in comparative oncology.

From Heston we learnt that lung tumours in the mouse are the most suitable for genetic study. There are sub-strains with high- and with low-pulmonary-tumour incidence. The genes which influence the development of induced tumours have the same effect on the development of the so-called spontaneous tumours. These are tumours with a high degree of heritability, and at least 10 known genes are connected with the increase or decrease in pulmonary tumours. After discussing the anatomy, histology and electron microscopy of the lungs of the animals most used in experimental research on lung tumours, Peacock directed attention to the double exposure of alveolar epithelium to carcinogens, on one hand, through the air breathed, and on the other through blood, which is responsible for conveying fat-soluble substances directly from the alimentary canal.

As the environment (broadly speaking) would seem to be important in pulmonary carcinogenesis, which may be supposed to overcome the body's defences, Bell examined the protective physiological mechanisms of the lung in small laboratory animals and birds, the respiratory physiology of which is little known or studied. Kinoshita reviewed recent progress in research on pulmonary carcinogenesis, and pointed out that many newly discovered causative agents for various species of animals have been introduced. The neoplasms are apparently alveolar and bronchiolar in origin, often undergoing squamous metaplasia. Even minute doses of the agents, given to pregnant or nursing mothers or to the progeny at birth, can be shown to produce lung cancer in mature age.

According to Roe, mice are not ideal for research on lung cancer in man, especially because of differences in airway size and mucus production; they represent, however, a valuable tool in that they make possible the study of a large number of animals and the rapid induction of pulmonary tumours. Such tumours are induced more easily with techniques which prevent the rapid elimination of the carcinogen from the pulmonary tissue. From this fact Shabad developed the theory that, in man, disturbances in the defence mechanisms of the lung could promote the deposition and the retention of carcinogens and the induction of tumoral proliferation. By histological analysis of pulmonary tumours of a number of different animals, by comparison between the lung tumours of the various species and comparison of these with human lung tumours, and by considerations of tumour classification, H. L. Stewart has been led to the conclusion that these are for the most part tumours that have not been studied in depth.

Spontaneous and So-called 'Spontaneous' Lung Tumours

Evidence points to the belief that spontaneous pulmonary tumours in animals are rare. In cattle they are exceptional (Migaki and Brandy; Montroni and Barboni), about 50 cases having been described (Owen); in the cat, according to Stünzi, they represent 12 per cent of all carcinomata; in the dog, where they do not seem to be on

the increase (Cohen), they occur in between 0.2 and 0.6 per cent of the autopsy material, respectively, at Richland (Washington) (Clarke *et al.*) and Storrs (Connecticut) (S. W. Nielsen). In both domestic animals (Dahme) and in captive wild mammals and birds (H. L. Stewart), the cases are usually of adenocarcinomata and squamous-cell carcinomata; alveolar-cell carcinomata are infrequent and are divided into unicentric and multicentric—the latter corresponding (Dahme) to pulmonary adenomatosis in sheep (jaagsiekte).

Because lung adenomatosis or foetalization frequently occurs in many circumstances and due to many causes, care (Schiefer) must be taken in formulating the diagnosis of adenomatosis, strictly defined, in sheep; its real nature is still doubtful, since the possibility of its being inflammatory cannot be excluded (Cohrs). Perhaps, in this regard, it is appropriate to consider the 'jaagsiekte complex' (Marsh) which consists of two morbid entities: (a) pulmonary adenomatosis in sheep (jaagsiekte), which may be a tumour capable of metastasising; (b) progressive chronic pneumonia, to which 'maedi' belongs. This latter disease (Gudnadottir) has appeared in sheep in Iceland in the past twenty-six years. It is a generalized infection which produces pulmonary lesions, lesions in the lymphatic system and probably in the central nervous system; it would seem that it may be transmitted to healthy animals by the coughing of affected animals. It is a virus disease, the fundamental characteristics of which we have now learned (Thormar).

Pleuropneumonia-like organisms have been shown in a series of sheep with adenomatosis, both serologically and culturally (Mackay). A lesion similar to adenomatosis in sheep (jaagsiekte) is found in man, and this is an alveolar carcinoma of the lung, which has a peculiar clinical progression (Cunningham). The so-called spontaneous lung tumours in mice (the lung tumours of inbred strains) are dependent on many factors, genetic and extragenetic. Johnson and Strong showed that, in all probability, it is possible to control the incidence of lung tumours, a genetically controlled biological characteristic, with selection on a maternal age basis. Rabotti reported on the biology of lung tumours in *BALB/cN* mice, a sub-strain of intermediate lung tumour incidence, and presented data on incidence (which can vary by extragenetic influence), progression and the findings by electron microscopy and tissue culture.

Induced Lung Tumours

It is possible to induce hyperplastic, metaplastic and/or tumoral lesions in the respiratory apparatus of animals in many ways.

(1) *Ionizing radiation.* After a review of lung carcinogenesis by ionizing radiation (Cember), papers were read on the possibility of obtaining tumours: (i) in the dog, with plutonium particles (Park *et al.*; Clarke *et al.*) and with X-rays (Andersen and Guttman); (ii) in the rat, with β -rays (Kuschner *et al.*); (iii) in the mouse, with X-rays at high altitude (Mori-Chavez).

(2) *Viruses.* Squartini *et al.* found indications that viruses and hormones might be involved in lung carcinogenesis in mice (*BALB/c/Cb/Se* sub-strain). Rabotti found viral particles in spontaneous lung tumours in mice of the *BALB/cN* sub-strain. The virus involved might be regarded as a possible environmental extragenetic factor in the development of lung tumours in mice of this sub-strain. Smith and Miller carried out research to show a virus in a transplantable tumour of mouse lung origin. In the hamster, with cultures of a human lymphoma containing a virus, S. E. Stewart obtained pulmonary lesions. Leuchtenberger and Leuchtenberger concluded from experiments on mice with influenza virus, and with influenza virus in combination with cigarette smoke, that influenza virus would appear to be an 'infectious' RNA virus, which under certain conditions may be implicated in malignant transformation

of cells. Such a conclusion supports the hypothesis that influenza virus may be a co-factor in the development of bronchogenic carcinoma. Harris and Negroni, in a series of experiments, similarly exposed mice to influenza virus and also to influenza virus in combination with cigarette smoke. The results with influenza virus alone gave a low incidence of malignant lung tumours developing rather late in the life of the mice; preliminary results with the combination of influenza virus and cigarette smoke indicate that tumours appear earlier. Of particular interest in the latter series of experiments is the appearance of a squamous cell carcinoma not unlike the lung tumours observed in human smokers. The authors do not regard their findings as conclusive.

(3) *Atmospheric pollutants*. Tumours: (i) in the rat, with nickel carbonyl (Sunderman), and with asbestos (in the pleura, mesothelioma) (Wagner); (ii) in fowls, with asbestos (axillary air-sacs) (Peacock); (iii) in the hamster, with asbestos (in the pleura, mesothelioma) (Smith), with benzo(a)pyrene by means of dust particles (Saffiotti *et al.*), and with cigarette smoke (metaplastic and papillary processes in the trachea and bronchi) (Dontenwill and Wiebecke).

Experiments in mice have yielded the following results: (i) with denicotinized tobacco smoke condensate (decrease in the development of pulmonary tumours by 3,4,9,10-dibenzpyrene) (Homburger and Treger); (ii) by the inhalation of tobacco smoke (after a year a single pulmonary tumour) (Harris and Negroni); (iii) with tobacco tar fractions (no increased incidence of pulmonary tumours) (Orr and Woodhouse). From the point of view of human pathology, Carnes and Moses reported that epithelial lesions have been studied, in autopsies, in relation to three forms of atmospheric pollution: (a) smoking history; (b) residence, classified by size; (c) occupation. Epithelial lesions of the trachea and bronchi proved to be more severe in those cases with a smoking history. According to Kreyberg, cigarette smoking, and to a lesser extent pipe smoking, may be considered to be particularly responsible for lung cancer.

(4) *Chemicals*. Tumours: (i) in the rat, with *N,N'*-2,7-fluorenylenebisacetamide and related aromatic amines (Morris), 9,10-dimethyl-1,2-benzanthracene, 3,4-benzpyrene and 3-methylcholanthrene (Crocker and B. I. Nielsen), 20-methylcholanthrene and 3,4-benzpyrene (Laskin *et al.*), *N*-methyl-*N*-nitrosourethane (Schoental); (ii) in the mouse *N*-nitrosodiethylamine and *N*-nitrosodimethylamine (Takayama and Oota), 4-nitroquinoline-*N*-oxide (Kinosita), 3-methylcholanthrene and 4-nitroquinoline-*N*-oxide, new-born and adult (Tsubura and Kimura), urethane (Tannenbaum; Ribacchi and Giraldo; at high altitude, Mori-Chavez), 'Imferon' (Langvad), hydrazine (Bianciffiori *et al.*) and its derivatives (Clayson *et al.*); (iii) in the hamster, with diethylnitrosamine (Dontenwill and Wiebecke); (iv) in the white Pekin duck, with methylcholanthrene (Rigdon).

In the rabbit, Griecute produced adenomatosis with dimethylbenzanthracene, and Moran showed that cortisone, administered after pulmonary lesions had been produced by chemicals, resulted in temporary hyperplasias of the epithelial type. In the pulmonary tumours of the rat by dimethylnitrosamine and diethylnitrosamine,

changes occur in the protein-levels which seem to reflect systemic alterations in the whole organism (Hoch-Ligeti). The various degrees of alkylation of nucleic acids in the lungs and in other organs of the mouse, hamster and rat after treatment with carcinogenic nitroso compounds were studied in relation to the susceptibility of the organ to the carcinogen (Magee).

Briand and Kieler investigated the carcinogenic and co-carcinogenic effect of various oxygen tensions on murine lung cells grown *in vitro*. Nitrosamines may be contained in cigarette smoke even though they have not been demonstrated; it is possible, however, that they disappear rapidly (Boyland and Roe). Urethane may act as an accelerator only (Bentvelzen and Szalay) and, according to Boyland, by means of *N*-hydroxyurethane. It has been shown in the rat that even a serious lesion in the pulmonary tissue is not sufficient for the development of a cancerous growth in the presence of a weak carcinogen (Stanton and Blackwell). Boeryd and Mellgren reported on the influence of heparin and epsilon-amino-caproic acid on pulmonary metastases of malignant tumours in mice.

Summary

In the final session of the conference, under the chairmanship of Lord Florey, Prof. Severi gave a summary of the contributions to the scientific programme. Little is known of the epidemiology, the biological behaviour and the pathology of spontaneous lung tumours in animals. The World Health Organization's programme in comparative oncology certainly is welcome. Attempts to induce tumours in the respiratory system by means of physical, viral and chemical agents must be developed extensively, so that research in the field of pulmonary carcinogenesis can be widened. On this point, Balò considered drugs capable of producing lung tumours in animals while Sprunt reported that, by irritation of the pulmonary epithelium with non-carcinogenic substances, lung tumours can be produced in the rabbit. The last mentioned is perhaps an important step for the understanding of pulmonary carcinogenesis. The results reported on experimental carcinogenesis by tobacco did not extend our knowledge beyond the known facts: that smoke condensate is a complete carcinogen, if a weak one, for the skin of the mouse and the rabbit, for the mouse cervix, for the subcutaneous tissue of the rat and also for the trachea of the dog. Nothing is known for sure of its carcinogenic action on the bronchial epithelium, perhaps because of the technical difficulties. A great deal is known about lung cancer in man, and a very great deal about so-called 'spontaneous' and induced lung cancer in animals, but the cause of lung cancer in man or of spontaneous lung cancer in animals remains obscure.

Prof. Severi agreed with Hockett that much systematic, methodical, step-by-step research with animal models must be done. So far as man is concerned, what is not understood cannot be prevented. For this reason there is little to expect from preventive medicine, but much to hope for from basic research.

The *Proceedings* of the conference will be published, as usual, by the Division of Cancer Research, P.O.B. 167, Perugia, Italy.

L. SEVERI

PLANNING A NEW MEDICAL SCHOOL

IN July 1964 the Minister of Health informed Parliament that a new medical school was to be established in the University of Nottingham, with an intake of 100 students a year, in conjunction with a new teaching hospital of 1,200 beds. For three years before this announcement, the University had been engaged in negotiations, during which much thought was given to the problems involved.

In October 1964 the University Council, at the request of the Senate, decided to set up a Medical School Advisory Committee to offer advice and recommendations to the University on medical education, teaching and research, on the best arrangements for the nature and lay-out of the buildings required, and on the University's administrative relations with other bodies concerned. The Com-

mittee's report has now been published*, and as the proposed new medical school is the first to be established in Britain since the Welsh National School of Medicine, set up in Cardiff in 1893, the report is of considerable interest.

The report begins with a brief review of medical education in the past and then discusses the purpose of a university medical school, which should, it considers, like the university itself, have two chief functions: the pursuit of knowledge and the education of the young—that of training for a profession, although a vocational objective, is added. It is accepted, as a fundamental tenet, that the new medical school will encourage research, particularly in the growing points of medical science, and also that teaching and research are complementary. The Committee adopts three guiding principles and attempts (1) to shape the pre-clinical part of the course to conform in pattern and objective with that of other science departments in the University; (2) to integrate and co-ordinate so far as possible pre-clinical and clinical departments and studies; (3) to plan the government, staffing and services of the hospital, to meet the needs of both the University and the community.

The curriculum and buildings of the new medical school should be designed in such a way as to develop and strengthen the links between: (1) the medical school and the rest of the University; (2) the pre-clinical and clinical parts of the school; (3) the hospital and the community it serves. The Committee suggests that the medical school and hospital should be known as the "University of Nottingham Medical Centre". Because teaching and research are so closely associated it is imperative that the new medical school should offer facilities for research in terms of time, space, staff, equipment and money which will attract only the best.

The total of 100 medical students per annum is accepted as the number at which the new school should aim, but the building should be flexible enough to enable this number to be increased. No dearth of good candidates is expected, but over-specialization at school has serious consequences for medicine. Boys and girls wishing to study medicine, who have passes in Advanced-level Examinations in both arts and sciences or arts subjects alone, should be encouraged; suitable arrangements should then be made to teach them the chemistry, physics and biology required for the study of medicine. Students should be selected for their intelligence (as revealed by Ordinary- and Advanced-level Examination passes) and for their personal qualities and capacity for citizenship, as shown by their school records and by interview. Every effort should be made to reduce the segregation from other students, inevitable to some extent in a medical student's studies, by sharing in common residence, meals, sports and social facilities. Every inducement should be given to students to incorporate themselves into the general life of the university. Certainly, the present science library should be extended to cater for medicine.

As regards the curriculum, the report suggests that this should be designed to cultivate a student whose curiosity is enhanced and not diminished, who is familiar with the broad field of medical science and who has

acquired the habit of learning. He should also have assimilated the ethos of medicine. The curriculum should be planned with the view of avoiding the chief defects of contemporary medical education, such as overcrowding, lack of integration between subjects taught at the same and different times, and too many examinations. Accordingly, it is recommended that lectures should not be excessive in number and attendance should, so far as possible, be voluntary. The student should have sufficient free time to read and work on his own initiative, both in the library and in the laboratory or wards. Details of the curriculum should be planned by an inter-departmental committee of teachers, appointed by the Faculty of Medicine with an independent chairman. This committee should include junior staff, and should seek opinion from students, and keep the curriculum continuously under review. To synthesize the contributions of different disciplines, lectures on different aspects of a single problem should be delivered consecutively and followed by group discussions. Clinical demonstrations should be given throughout the pre-clinical period so as to emphasize the unity of knowledge and alleged vocational aspects of the curriculum, but it should not be allowed to dominate the educational aspects. Medical examinations should be reduced to the minimum compatible with the regulations of the General Medical Council.

It is suggested that the curriculum should consist of a period of three years' training for the biological scientist, whose interest is centred on man, followed by two years of clinical training and two pre-registration years. For those students who have not studied science at school, the University should provide an introductory year of science. The first-degree course in medical biological sciences is visualized as forming the third limb of a tripod, of which the other two would be a school of general biological sciences, within the faculty of pure science, and a school of agricultural biological sciences within the faculty of agricultural sciences. The teaching hospital should provide for the needs of the community and of the University and its services, and include geriatrics, psychiatry and infectious diseases in a certain area. The size of the units may require modification to meet the teaching and research needs of the University. The teaching hospital and medical school should be designed and constructed as a unit, to permit as free as possible an interchange of people and a maximum flexibility. It is suggested that the governing body of the new teaching hospital should be constituted by the Regional Board and the University (as equal partners), and that it should be responsible for obtaining the necessary finance from the Ministry of Health and the University Grants Committee. It is also recommended that the Department of Community Health should contain a sub-department of general practice, the function of which would be to help in the organization of general practice in the area, and to encourage the provision of better working conditions for general practitioners and thus better service for patients. The medical school and the teaching hospital should be designed as an entity. The Committee would regard a start in temporary accommodation as both extravagant and undesirable, as it may result in loss to the University of some of the best senior staff—on whom the future of the medical centre depends.

NATURE CONSERVANCY IN BRITAIN

IN a paper, "Advances in British Nature Conservation", now preprinted from the Society's handbook for 1965*, Mr. E. M. Nicholson, director-general of the

* Society for the Promotion of Nature Reserves. *Advances in British Nature Conservation*. (Preprint from the Society's Handbook for 1965.) By E. M. Nicholson. Pp. 16. (London: Society for the Promotion of Nature Reserves, 1964.)

Conservancy, summarizes some of the recent changes in the concepts, practices and scale of conservation of natural areas in Great Britain in recent years.

Conservation has now ceased to be the affair of a local minority and has become a major nation-wide project. The vague idea that reserves are a good thing and

valuable to naturalists has been replaced by a concept of their role as living museums, and outdoor laboratories, to be fully and systematically studied by scientists, with the view of understanding their ecosystems, biological productivity, population dynamics, successional and land-use history, and so forth. The assumption that any necessary management of reserves can be satisfactorily achieved empirically has been replaced by a comprehensive, two-tier programme of concerted basic and applied ecological researches, designed to elucidate the full range of fundamental principles involved, and to develop the necessary series of techniques and prescriptions for their application. It is also now recognized that not only natural and semi-natural habitats displaying various stages of ecological succession are equally deserving of care and protection in the interests of science, but also modified or induced ecosystems and sites, already used for, or well suited to, ecological investigations. Local distributions are now being systematically and comprehensively mapped, as well as changes and trends in populations. The lack of interest of universities in ecology and conservation has been replaced by a rapid growth of specialized postgraduate courses, and there has been a major increase in the number of students taking doctorates in ecological subjects and a general growth in university field studies, partly at the centres of the Field Studies Council.

The essential role of basic and applied ecology in the training and practice of the land professions, such as forestry, agriculture, fisheries, estate management, land-

scape architecture and town and country planning, is now becoming recognized, as well as the need for increased understanding of the character, scale and causes of human impacts on Nature, both through studies and analysis and through improved communications between the different interests concerned. Applied ecology is now recognized as being the guidance of the proper control of the use of potentially polluting substances, such as toxic chemicals, as well as the promotion, through concerted action and the wise multi-purpose use of land and natural resources, of the general adoption and observance of modern conservation practices.

Mr. Nicholson's thesis is that scientific ecology has now reached the point of transforming the concepts of management of natural areas, and is beginning to make a serious impact on the use and management of land, education, and interests concerned with the use of renewable natural resources. He illustrates this by summarizing the British contribution on an international plane and by reviewing the position in the various counties of England and Northern Ireland. The distinction between conservation movements in Britain and other countries is based far more on the naturalist tradition, on which professional work in biology has lately been superimposed. The centre of gravity of the whole movement is shifting steadily from the saving of species, and even of habitats, to a broader view of conservation as involving the scientific care and good management of man's entire natural environment.

ORIGIN OF ATYPICAL METEORITES FROM THE ARIZONA METEORITE CRATER

By PROF. MICHAEL E. LIPSCHUTZ

Department of Chemistry, Purdue University, Lafayette, Indiana

THE well-known Arizona Meteorite Crater is an impact feature having a diameter of nearly 1 km. Estimates of the mass of the meteoroid which produced it have ranged from 30,000 (ref. 1) to 2.6 million² metric tons. The (spherical) diameters corresponding to these estimates are 20 m and 86 m. The main mass of this meteoroid has never been located. Inasmuch as most of the meteoroid probably vaporized or mixed with the surrounding rock during the explosion, it seems rather unlikely that much of the mass will ever be found. However, a fraction did survive the explosion in the form of many thousands of fragments ranging up to 640 kg in weight. The overwhelming preponderance of these have been 'normal' coarse octahedrites with kamacite band-widths ranging up to 4–5 mm. Less than 12 of the recovered fragments had structures corresponding to those of medium octahedrites. These atypical meteorites have been called Canyon Diablo No. 2, Canyon Diablo No. 3 and Monument Rock³. There is no doubt that these three types differ significantly both from the normal Canyon Diablo meteorites and among themselves⁴ in structure and chemical composition.

Four explanations have been offered which can account for the atypical samples. The first of these is that the meteoroid was not a solid mass on impact with the Earth but consisted of a swarm of much smaller objects⁵. The possibility of such a swarm seems rather remote⁶, and will not be considered further here. A second possibility is that the meteoroid consisted of a main mass of coarse octahedrite structure and several satellites with the medium octahedrite structures³. A third explanation is that there were four distinct falls: a large crater-forming coarse octahedrite mass, followed by three separate medium octahedrite falls³. The fourth possibility is that

all were part of the same mass which had varying physical structures and minor element contents^{6,7}.

Until recently, no definitive results had been obtained as to which of these explanations was correct. On the basis of cosmogenic rare-gas measurements⁸, Heymann was able to show that Canyon Diablo No. 2 was probably buried in the main mass of the meteoroid and exposed to cosmic-ray bombardment for 540 ± 100 million years at a pre-atmospheric depth of 50 cm. The remote possibility, however, existed that it was a distinct fall with a cosmic-ray exposure age of 64 ± 12 million years. The results of the rare-gas measurements on Canyon Diablo No. 3 were rather less conclusive. Either this meteoroid was part of the main mass and had an exposure age of about 1,000 million years or it was originally in a 10^5 kg object having an exposure age of 540 ± 100 million years (either a protuberance on the main mass or as a separate 10^5 kg mass). Similar alternatives⁷ were proposed in order to explain the observed rare-gas contents of sample 24, a normal Canyon Diablo. However, a subsequent $^{40}\text{K}/^{41}\text{K}$ measurement by Voshage⁹ of sample 24 yielded a value in substantial agreement with the exposure age of 540 million years. This result casts considerable doubt on the validity of the exposure age of 1,000 million years for Canyon Diablo No. 3. Most of the known measured medium octahedrites have exposure ages in the 500–600 million year range^{8,9} and it is therefore not possible from Heymann's measurements to decide whether Canyon Diablo No. 3 was located in a 10^5 kg projection from the infinite mass ($\gg 2 \times 10^5$ kg) meteoroid or was a separate fall. A number of recent investigations^{3,7,10} have established the fact that all known normal Canyon Diablo meteorites found on the Crater rim have been shocked to at least 130 kb. Since all three atypical types were recovered

Fig. 1. Comparison between the apparently normal, undeformed Widmannstätten pattern of the moderately shocked Canyon Diablo No. 3 sample (left) with the faint deformed pattern of the heavily shocked Canyon Diablo No. 2 (right). The white areas on the polished surface of the Canyon Diablo No. 3 are ϵ iron

Fig. 2. Microstructure of the lightly shocked Monument Rock meteorite showing deformation bands (D) and Neumann bands (N). The bar in these figures is 0.1 mm

from the north-east rim¹¹ it seemed reasonable to examine them for shock effects in an attempt to resolve the question of their origin.

With the help of Prof. C. B. Moore, curator of the Nininger Meteorite Collection, I obtained samples of Canyon Diablo No. 2 (371.3), Canyon Diablo No. 3 (586.1), and Monument Rock (587.1x). The first two of these are shown in Fig. 1. Monument Rock is illustrated in Plate 22, Fig. 2E of ref. 3. These samples were polished and examined by standard metallographic techniques. The detailed interpretation of shock-induced metallographic changes in meteoritic iron have been described previously^{7,10} and need not be repeated here.

Monument Rock. This meteorite falls into the lightly shocked category (< 130 kb) of Heymann *et al.*⁷. The large number of Neumann bonds (shock twins) in it has previously been noted by Nininger³. The only evidence for any unusual shock is the presence of small deformation bands (Fig. 2) in the kamacite (α -iron). There were no inclusions in the exposed surface which could be studied crystallographically for shock effects.

Canyon Diablo No. 2. This meteorite falls into the heavily shocked category (> 750 kb) of Heymann *et al.*⁷. The Widmannstätten pattern is indistinct (Fig. 1) and the kamacite is entirely recrystallized (Fig. 3). The cohenite (Fe_3C) grains show diffusion borders of pearlite. Some ledeburite-like eutectic is present and the rhabdites (Fe_3P) in the hotter end of the sample are redissolving. The taenite (γ) and plessite ($\gamma + \alpha$) grains are partially or completely clear and there is a secondary kamacite precipitate in some of them. That these thermal effects are due to shock and not to contact with hot ejecta or artificial heating is proved by the crystallo-

graphic character of the cohenite, which has been shocked to about 1,000 kb¹².

Canyon Diablo No. 3. This meteorite falls into the moderately shocked category (130–750 kb) of Heymann *et al.*⁷. The Widmannstätten pattern is quite distinct and undeformed although the macrostructure shows areas of ϵ iron (Fig. 1). Pressure gradients are very common. Some kamacite areas show normal Neumann bands, while others show regions of finely recrystallized kamacite around inclusions, or areas of completely recrystallized kamacite. Some of the patches of ϵ iron are normal, while others are in the process of conversion to polycrystalline kamacite (Fig. 4). The rhabdite and schreibersite (Fe_3P) grains are apparently thermally unaltered. Some cohenite grains show borders of martensite, but most exhibit no carbon diffusion

zones. The taenite and plessite regions are clearing and there is a secondary kamacite precipitate in some taenite bands: the exposed troilite (FeS) nodule of the coarse type 2 variety. A systematic crystallographic study of the cohenite grains in this sample is not yet complete. Those specimens studied thus far fall into the 400–500 kb range so that there seems little doubt that portions of this meteorite were shocked to pressures of at least 500 kb.

It is regrettable that the results from the Monument Rock sample permit no absolute conclusion regarding the origin of this meteorite. It could have been part of

Fig. 3. Microstructure of the heavily shocked Canyon Diablo No. 2 sample showing polycrystalline kamacite (K) and pearlite diffusion border around the cohenite (C)

Fig. 4. Microstructure of the moderately shocked Canyon Diablo No. 3 showing ϵ iron beginning to recrystallize, particularly on the left at the interface between the cohenite grain and the iron

the main mass, a satellite of it, or a separate fall. However, it should be pointed out that it is indeed a unique sample. Not only is it the only known specimen of its type found at the Crater site but it is also the only known exception to the observation that rim samples (whether of the normal or atypical varieties) have been moderately to strongly shocked.

An unambiguous conclusion can be reached, however, regarding the origin of both Canyon Diablo No. 2 and Canyon Diablo No. 3. These meteorites were involved in a catastrophic explosion during which they were shocked and therefore heated. The narrow widths of the carbon diffusion borders around the cohenite grains indicate that the duration of reheating was short, at most a few minutes, and that the meteorites cooled quickly to below the γ - α transformation temperature. Thus, their immediate post-shock mass was not considerably larger than their recovered mass. These characteristics are the same as those of the normal shocked Canyon Diablo meteorites. It seems very highly probable, therefore, that both Canyon Diablo No. 2 and Canyon Diablo No. 3 were located in the interior of the meteoroid during the instant

of its explosion and were therefore neither satellites of the main mass nor separate later falls. It seems, therefore, reasonable to regard as proved the earlier suggestion^{6,7} that chemical and structural variations do exist in iron meteorites over distances of less than 100 metres.

MECHANISM OF STORED-ENERGY RELEASE AT 200° C IN ELECTRON-IRRADIATED GRAPHITE

By PROF. E. W. J. MITCHELL and M. R. TAYLOR

J. J. Thomson Physical Laboratory, University of Reading

THE release of stored energy from reactor-irradiated graphite is of considerable physical and technological interest and has been extensively examined. The results are contained in a large number of papers, most points being covered in the following conference *Proceedings*: the first Geneva Conference on the "Peaceful Uses of Atomic Energy" (1956); the fifth Carbon Conference (1962); the C.E.G.B. Berkeley Conference on "The Properties of Reactor Materials" (1962); and the I.A.E.E. Conference on "Radiation Damage in Reactor Materials" (1963).

For irradiations of low neutron doses the energy is released primarily in the well-known 200° C peak in the warm-up curve, although there is a tail to the curve extending to much higher temperatures. Samples irradiated to higher neutron doses, or at higher irradiation temperatures, release relatively less energy in the 200° C peak, compared with the higher temperature region¹. The energy release has been related to neutron dose and temperature systematically by Bell *et al.*².

The origin of the 200° C peak has remained uncertain. Although there had originally been suggestions that it arose from the recombination of interstitial atoms and vacant sites^{3,4}, more recently it has been generally considered that the energy was associated with a re-arrangement of displaced atoms in which the vacancy concentration was not significantly altered. The types of model which have been considered may be illustrated by referring to those put forward by Bollman⁵ and Iwata and Suzuki⁶. Bollman has suggested that the process involves the recrystallization of small amorphous regions of up to 60 Å diameter which he assumes are produced by neutron irradiation. According to Bollman, the recrystallized regions may contain some dislocation dipoles, but the region is considered to be of much lower energy than the amorphous region.

On the other hand, it has frequently been suggested that the stored energy is released when interstitial atoms re-arrange themselves between graphite planes into a lower energy configuration. In the Iwata-Suzuki model⁶ it is assumed that relatively loose aggregates of C₂ molecules have formed at about room temperature. These

aggregates are assumed to produce the c-axis unit cell expansion and to be loosely held together through the elastic strain, the electronic binding between the C₂ molecules being assumed to be small. At 200° C, Iwata and Suzuki suggest that this loose configuration is converted into the much more stable configuration of the tongue dislocation—not unlike Bollman's dislocation dipole—with a considerable release of energy. Such a process would be accompanied by a recovery in unit cell expansion but the crystal would remain longer than before irradiation.

Each of these models possesses the feature that some disordered arrangement of carbon atoms is converted into a more or less perfect crystal without any interstitial-vacancy recombination occurring. Normal graphite has a relatively large interplanar spacing in the c-direction and the binding between planes is weak. We expect that the differences between elastic strain energies associated with various interstitial combinations will be small. Energy differences between different structures will then arise primarily from the electronic terms. These can be treated as more or less isolated from the rest of the crystal such that a two-dimensional perfect structure between the planes would have an energy not very different from a two-dimensional layer in the perfect crystal. We can therefore expect that the energy gain from the re-arrangement of the interstitials will be less than the energy required to dissociate graphite into free carbon atoms in their *tr*.³ π graphite valence state. Accordingly, from such models the stored energy (*S*) will be expected to be less than the sum of the heat of sublimation (*E_s*) and the promotional energy (*E_p*):

$$S < E_s + E_p = 7.44 \text{ (ref. 7) } + 6.93 \text{ (refs. 8 and 9) eV}$$
 per atom involved in the ordering process, or *S* < about 14–15 eV, there being uncertainty in *E_p*.

In order to decide by how much *S* is less than 14–15 eV on these models we have to specify the electronic state of the distributed interstitials before re-arrangement. If their electronic state were not *tr*.³ π but tended more to the free atomic state ³*P*, then *S* would tend to 7.44 eV (*E_p* → 0). Similarly, if pairs resembling C₂ molecules

between the planes are the starting point of the re-arrangement we should expect $S \approx 7.44 - 3.03 \approx 4.4$ eV/atom, since 3.03 eV is the energy release per atom for the formation of C_2 from carbon atoms in 2P states¹⁰. Thus, while precise values of S cannot be calculated without considerable difficulty for different interstitial re-arrangement models, we can say with fair certainty that $S < 14-15$ eV and in a plausible case we find $S \sim 5$ eV.

The process of radiation damage by reactor irradiation is complex, and it has not been possible to determine accurately from the stored-energy measurements the amount of energy released per atom involved in the process. During the past three years we have been engaged on measuring the energy release in electron irradiated graphite. The objects have been, first, to determine whether the 200° C peak is present—we should not expect to see it if Bollman's hypothesis were correct because of the very much lower mean carbon recoil energy resulting from 2.0-MeV electron irradiation (mean recoil about 131 eV) compared with neutron irradiations (mean about 10⁵ eV). Secondly, if the peak were found we should be able to determine the energy involved per original displacement event, the number of which can be calculated in an electron irradiation with much more certainty than in a reactor irradiation. The experiment has now been completed and in this article we give a preliminary account of the results.

Stored-energy determination. An adiabatic differential power method was used to measure the stored energy released on annealing between 20° C and 400° C. The principle of operation is similar to that of Clarendon et al.¹¹, and to the linear-rise calorimeter of Henson and Mounsey¹². Two specimens, one irradiated, the other unirradiated, were mounted in a cavity which was heated at approximately 6° C/min. Individual heaters mounted axially in each specimen were used to maintain both specimens at the same temperature as the cavity. The difference in the power supplied to the two heaters was measured between 20° C and 400° C. After the initial run the calorimeter was allowed to cool, and then a second run was performed to establish the small power difference which was necessary in the absence of any stored-energy release. The stored-energy release was obtained by subtracting the power difference required in the second run from that required in the first run. Individual runs were reproducible to within ± 0.001 cal deg⁻¹ g⁻¹. The performance of the apparatus was checked by carrying out an experiment in which some small pieces of copper were introduced into one of two unirradiated graphite samples. Full details of the method and the various precautions which have to be taken will be published later.

The specimens, which were of reactor grade A graphite, were irradiated with 2.0-MeV electrons from the University's Van de Graaff accelerator, two specimens at 95° C and the remainder at 65° C. The irradiation flux was $7.7 \mu\text{amp cm}^{-2}$ (4.9×10^{13} e⁻ sec⁻¹ cm⁻²) and the specimens were irradiated in four directions, the maximum dose used being $1.87 \times 10^5 \mu\text{amp min cm}^{-2}$ (7.0×10^{18} e⁻ cm⁻²) in each direction. This was done to ensure as uniform as possible a distribution of damage throughout the thick specimens. Five specimens, irradiated to the different doses shown in Table 1, have been measured.

Calculation of the number of displacements. The concentration of displaced atoms has been determined using

the cross-sections computed by Mitchell and Salisbury¹³ for the displacement energy (E_d) of 60 eV indicated by the electrical resistivity measurements of Lucas and Mitchell¹⁴. The latter experiments showed that the displacement energy must be greater than the commonly assumed 25 eV and their analysis of the energy dependence of the resistivity changes indicated a value of 60 ± 10 eV. In using this cross-section (σ_d , column 20 of Table 1 of Mitchell¹⁵) we have allowed for the production of displacements by the more energetic primary knock-ons¹⁶⁻²⁰. The energy-loss of the electrons in the specimens has been estimated from the range-energy relation as previously described by Clark *et al.*¹⁶. The results are shown in column 2 of Table 1; they correspond to the production in the present conditions of 0.30 displacements cm⁻³ per incident 2.0 MeV e⁻ cm⁻².

It has been suggested by Goggin and Reynolds¹⁷ that close interstitial-vacancy pairs have less effect on the electrical resistance than separated defects. If close pairs were preferentially produced at low energies in the Lucas and Mitchell experiment they would have the effect of making the estimate of $E_d = 60$ eV too high. Current calculations suggest that it would be unlikely that this effect could reduce the value to as low as 50 eV, the effect of which would be to increase the number of defects in the crystal above that calculated ($0.30 \text{ cm}^{-3}/\text{e}^- \text{ cm}^{-2}$) to at most 0.41.

This is one of the various sources of error considered, and their net effect is difficult to estimate precisely. The details of the discussion of errors will be included in the fuller publication. The conclusion is that 0.30 displacements cm⁻³/e⁻ cm⁻² is our best estimate (column 2) and that although the true value might be higher it is unlikely to be as high as 0.41.

Results and discussion. The results of the stored-energy measurements are given in column 3 of the Table in cal/g. Further methods of computing the stored energy in the 200° C peak from the results are being examined, and these may lead to some minor adjustments to the values given here. In subsequent columns the results are expressed as energy in eV per incident electron, and in eV per displaced atom. The slope of the best line of energy versus defect concentration gives a mean value of 13.5 eV per original displacement. (For a displacement energy of 50 eV we would obtain 9.9 eV per original displacement.)

Thus from measurements on electron-irradiated specimens we find that: (a) there is an energy release peak at 200° C; (b) the total energy released in the peak is 3.0 eV per incident 2.0-MeV electron; and that, combining this result with the calculation of the number of displaced atoms, (c) using a displacement energy of 60 eV the energy released in the 200° C peak can be expressed as 13.5 eV per original displaced atom.

The observed energy release in electron-irradiated graphite cannot be explained by Bollman's mechanism. Furthermore, the value of 13.5 eV per displaced atom makes it improbable that the results can be explained by the aggregation of interstitial C_2 molecules for which we have argued that the energy release should be about 4-5 eV. Indeed, it seems impossible to account for the derived value of 13.5 eV per displaced atom without assuming the recombination of interstitial atoms and vacancies. In the following discussion we give reasons for assigning the value of 13.5 eV per displaced atom to interstitial-vacancy recombination.

(1) Lidiard and Perrin²¹ have shown in their analysis of the kinetics of the dimensional changes in neutron-irradiated graphite that recombination has to be taken into account at 150° C.

(2) Using the same cross-sections as those used in calculating the concentrations given in column 2, we find that for the flux used in our experiments of 4.9×10^{13} e⁻ cm⁻² sec⁻¹ we produce 1.5×10^{13} displacements cm⁻³ sec⁻¹. It is generally agreed that interstitial migration occurs between atomic layers in graphite with little diffusion across

Table 1. SUMMARY OF RESULTS FOR ELECTRON-IRRADIATED POLYCRYSTALLINE GRAPHITE

Electron dose (e ⁻ cm ⁻²)	Concentration of displaced atoms ($E_d = 60$ eV) (cm ⁻³)	Stored energy released between 20° and 400° C (cal g ⁻¹)	Stored energy released per incident 2 MeV electron	Stored energy release per original displacement
			eV per incident e ⁻	eV per displacement
1.7×10^{18}	0.53×10^{18}	1.9 ± 0.2	3.4	$15 \pm 3^*$
3.4×10^{18}	0.97×10^{18}	2.4 ± 0.2	2.4	11 ± 2
		2.9 ± 0.25	2.9	13 ± 2
5.3×10^{18}	1.6×10^{18}	5.3 ± 0.1	3.1	14 ± 2
7.0×10^{18}	2.1×10^{18}	6.8 ± 0.1	3.1	14 ± 2

* These are the estimated overall uncertainties.

the layers. In the experiments recorded here, therefore, we expect that displacements were produced at the rate of 5.1×10^5 per cm^2 per interatomic layer per sec.

(3) A single interstitial will diffuse rapidly at 338° K and, using the activation energy of 0.45 eV determined recently by Davies and Mitchell²² from their detailed analysis of the reverse annealing peak, we find that an interstitial will jump at the rate of 2.0×10^6 per sec (assuming a frequency factor of 10^{13} sec⁻¹). For the lower activation energy derived theoretically⁶ we should get an even higher jump frequency.

(4) In electron-irradiated polycrystalline graphite in which the displacements are produced primarily as single interstitial-vacancy pairs, we now consider the obstacles to interstitial aggregation. The most likely obstacles are the grain boundaries the separation of which is about 10^3 Å. In fact, it has often been assumed (for example, Goggin and Reynolds¹⁷) that interstitials cannot pass through a grain boundary for temperatures of about room temperature and below. The grains define an interlayer volume of 3.4×10^{-18} cm³ and an average number of jumps of about 10^5 for an interstitial produced in this volume to reach a boundary.

(5) For an interstitial diffusing with a jump rate of 2×10^6 sec⁻¹ the vicinity of a grain boundary would be reached after 5×10^{-2} sec. This is very much shorter than the time interval between the production of interstitials in the interlayer volume by the irradiation, given by $(5.1 \times 10^5 \times 10^{-10})^{-1}$ or 2×10^4 sec.

Thus in the case of electron irradiation, defects are not produced sufficiently rapidly, within a mutually accessible volume, for diffusive interstitial aggregation to occur. We consider that the interstitials are most likely to be trapped in the vicinity of grain boundaries. Other obstacles or trapping points may be operative and similar conclusions could be drawn for dislocation trapping and impurity trapping (reactor grade A graphite may contain up to 50 p.p.m. of some impurities).

We propose, therefore, that during our irradiation at 65° C interstitial atoms become trapped singly in the vicinity of one or more of the obstacles and that interstitial-vacancy recombination does not occur at 65° C. In the region of the 200° C peak we suggest that these trapped atoms are released and that, predominantly, recombination occurs. This is expected because initially the number of accessible vacancies will be greater than the number of free interstitials. Undoubtedly a small amount of interstitial aggregation could occur. The activation energies involved in the process (a spread of about 0.2 eV around 1.38 eV from our measurements) corresponds to the spectrum of interstitial-obstacle binding energies. Our conclusion is that the 13.5 eV per atom derived from our experiment corresponds to the energy associated with interstitial-vacancy recombination in graphite. From the difference between the detrapping activation energy (1.38 eV) and the interstitial migration energy (0.45 eV) we estimate that the energy to form a Frenkel pair in graphite is $(13.5 + 0.93) \approx 14.4$ eV. (For a displacement energy of 50 eV we would find the formation energy to be 10.8 eV.)

It is interesting to note that Coulson *et al.*⁹ calculated the formation energy of a Schottky defect, in which the ejected atom is on the surface, in graphite to be 10.7 eV. If the atom had been put in an interstitial position the energy of formation would have been higher. Thus, although we should not over-emphasize the agreement, it is encouraging that the value we obtain for the stored-energy release per interstitial vacancy recombination is consistent with Coulson's calculation.

The mechanism described here does not affect the explanation put forward by Goggin and Reynolds¹⁷ of the reverse annealing peak which is found after electron irradiation below 80° K. In this case the interstitial atoms are immobile at the temperature of irradiation so that the interplanar concentration of interstitials may

grow. When the interstitials become mobile simple aggregates may be formed.

Finally, we comment on the significance of our conclusion to the interpretation of the stored-energy release in the 200° C peak in neutron-irradiated graphite. For three low-dose neutron irradiations up to 2.5×10^{18} fast n° cm⁻² Ni scale we have measured the release of stored energy in our apparatus and find, for example, 21.5 cal g⁻¹ at a dose of 2.5×10^{18} , and a mean of 0.9 cal g⁻¹ per 10^{17} fast n° cm⁻². Åstrom²³ reported 5.3 cal g⁻¹ for a thermal dose of 3.8×10^{18} and an estimated fast dose of 3.8×10^{17} (1.4 cal g⁻¹ per 10^{17} fast n°). We cannot be certain about the comparability of the fast dose estimate, and in view of this the two measurements are in reasonable agreement. For our experiment and using the damage function of Thompson and Wright²⁴ we find that the energy release corresponds to about 2 eV per displaced atom. In the reactor irradiation we expect the energy per displaced atom to be less than the value of 14 eV per interstitial-vacancy recombination discussed already because: (1) some multiple interstitial groups are expected to be produced directly by the irradiation; (2) the higher effective damage flux means that there is a much greater chance of interstitial aggregates forming by diffusion. (This is the basis of the homogeneous theory for the nucleation of dislocation loops used by Reynolds and Thrower²⁵ to account for the observed rates of growth in high neutron fluxes.)

Both these factors mean that, relative to the total number of interstitials produced, fewer single interstitials will be trapped by obstacles. Thus only a fraction of the interstitials will be a source of stored energy when they are released in the 200° C peak. Furthermore, continuing re-arrangements of the various interstitial aggregates would yield some stored-energy release on the high-temperature side of the peak. At the highest neutron fluxes the fraction of trapped single interstitials will become progressively smaller and the stored-energy release at 200° C will become a relatively smaller part of the whole.

Conclusions. The stored-energy release in electron-irradiated graphite corresponds to 13.5 eV per displaced atom. The major uncertainty in this value comes from the calculation of the defect concentration which may be too low.

It is shown that, for the electron-beam currents used, an interstitial atom moving between graphite layers could be trapped by grain boundaries, dislocations or impurities long before the production of the next interstitial by the electron in the appropriate volume (for example, interatomic layer in a crystallite). Thus interstitial aggregates will not accumulate and we interpret the measured stored-energy release in the 200° C peak as the recombination of interstitial atoms and vacancies, the interstitials being freed with a range of activation energies around 1.4 eV.

In reactor-irradiated graphite we expect that relatively fewer interstitials are trapped in this way, other interstitial formations occurring because of the higher recoil energies involved and the much higher effective damaging flux. Thus, although the same process of interstitial-vacancy recombination is assumed to be the major contribution to the stored-energy release at 200° C, the energy involved per original displacement is considerably less. This will be true particularly at high fluxes, and the fraction of the total stored energy released in the peak will become progressively smaller as irradiation flux and temperature are increased.

The proposed model therefore accounts for the qualitative features of the energy release in reactor-irradiated graphite. The value of about 14 eV per interstitial-vacancy recombination deduced from electron-irradiated graphite is consistent with the vacancy formation energy of 10.7 eV calculated by Coulson *et al.*⁹. In the latter case the ejected atom has been put on the surface and the defect formation

energy would be higher if the ejected atom remained in an interstitial position.

We wish to thank the Atomic Energy Research Establishment for a grant which enabled this work to be carried out.

SOME CHARACTERISTICS OF TROPICAL THUNDERSTORMS

By PROF. S. V. C. AIYA

Department of Electrical Communication Engineering, Indian Institute of Science, Bangalore

THE parameters of atmospheric noise necessary for assessing its interfering effect on the reception of radio signals¹⁻³⁴ have been investigated extensively at Poona (18°31' N., 73°55' E.) and Bangalore (12°58' N., 77°35' E.). Such investigations have resulted in the development of techniques for following the activity of thunderstorms. The data collected are found to be useful for drawing inferences on the characteristics of thunderstorms.

A thunderstorm is a localized thermodynamic process in the atmosphere accompanied by electrical discharges. Its activity is ordinarily dealt with in terms of a 'thundercloud'. If the base area of a thundercloud is idealized to a circle, it could be said that the radius ordinarily lies between 10 and 20 km. The area involved is about 1,000 sq. km or less. Thunderstorms can be classified into various types, namely, local, frontal, etc. The area involved in a local storm may approximate to that associated with a single thundercloud. The area involved in the activity of a frontal type of storm is, at least, ten times larger. That is, the radius of the circle within which there is activity may be 50-100 km. In a frontal type of storm, it is just possible that several thunderclouds in several regions of the large area involved become active; but they may become active during different hours of the day. The duration of activity may vary from one thundercloud to another. At any one time of day, more than one thundercloud may be active but they may be in different stages of activity. All the possibilities indicated could be regarded as random phenomena but they may not be quite independent of each other. Hence, any investigation of the activity of a frontal storm as a whole involves the integrated study of several thunderclouds.

When a thundercloud is active, lightning occurs. This is observed to consist of a series of intermittent flashes over a period of time which may extend from a fraction of an hour to several hours. Lightning flashes are accompanied by electrical discharges, and give rise to electrostatic, induction and radiation fields. At great distances, the radiation field preponderates. Even at close distances, the electrostatic and induction fields can be ignored if measurements are taken over a narrow band at a chosen high frequency. Such measurements enable a study of lightning flashes through their radiation fields only at all distances.

Lightning flashes are known to occur inside the cloud, from cloud to cloud, from the cloud into the air, and from

the cloud to ground. Electrical discharges within the cloud constitute a very essential feature of all types of flashes and they are now known to give rise to the radiation fields at high frequencies. For most flashes, the discharge channel is, for practical purposes, approximately vertical. Some flashes, particularly those of the cloud to cloud type, have long horizontal sections; but even such flashes have been found to give rise to significant vertically polarized radiation. Hence, a simple vertical aerial can be used to pick up the high-frequency radiations from lightning flashes.

At tropical latitudes, the cloud base is ordinarily about 3 km above the mean sea-level. Cloud discharges, therefore, radiate from a height of this order. Direct ray reception of the narrow-band high-frequency radiation can, therefore, be expected for source distances up to about 300 km. This enables the activity of a local frontal storm to be followed by signals unaffected by attenuation due to propagation.

The duration of a flash, the time interval between successive flashes, and the power radiated by a flash are some of the useful parameters for this purpose. The integrated value of the radiation fields due to a flash at a predetermined distance is a measure of the power radiated by a flash. Numerical values of the parameters vary in a random way. Their distributions over a short period (a few minutes) have to be studied so that the statistically computed values can be utilized in following the activity of storms. Statistical studies have shown that the arithmetical average value of a parameter during a 5-min period is adequate. Thus, the time interval between successive flashes can be replaced by the rate of flashing, that is, the number of flashes/min, and the power radiated by a flash, by the arithmetical average value of the integrated radiation fields due to a flash for the 50 flashes of the highest intensity received during the 5-min period and so on.

The growth and decay of the activity of a thundercloud are reflected in corresponding changes of the rate of flashing. In an active thundercloud, a decaying convection cell gives rise to a new cell and this process continues until the thundercloud itself decays. Growth and decay of the cells thus produce a cyclic variation in the rate of flashing. Hence, the lifetime of a thundercloud, the lifetime of a convection cell and the number of such cells developed during the lifetime of the thundercloud, etc., can be determined from studies of the rate of flashing.

The duration of a flash varies with the growth and decay of the activity of a thundercloud and is minimal when the activity has reached its peak. The power radiated by a flash also varies but becomes maximal when the activity has reached its peak. The random variation of the integrated value of the radiation fields arising from a flash when measured at one predetermined distance lies within certain limits. Surprisingly, the range of variation due to changes of distance of the flash even for a locally active frontal storm lies within these limits. Hence, the effect of variations of distances of flashes on field-strength measurements can be neglected.

Radiation from a lightning flash, when picked up by a vertical aerial and fed to a superheterodyne receiver tuned to a high frequency, gives rise to a noise burst at the output of the detector. When measurements are carried out, the receiver is aligned to a selected bandwidth and operates with its automatic gain control switched off. By carefully adjusting the sensitivity of the receiver, it is possible to investigate exclusively the noise bursts arising from either a locally active thundercloud or a locally active frontal type of storm.

A noise burst as described is the counterpart of a lightning flash. The number of noise bursts recorded per minute is a measure of the rate of flashing. An indirect indication of the power radiated by a flash is obtained by measuring the integrated radiation fields for the duration of the corresponding noise burst. The duration of a noise burst corresponds to the duration of a flash and the time interval between successive noise bursts corresponds to the time interval between successive lightning flashes. The activity of thunderstorms can, therefore, be followed by studying the characteristics of the noise bursts arising from them.

Noise-burst measurements have been carried out in three ways, namely, by using (a) a high-sensitivity, high-fidelity level recorder^{14,21}; (b) a noise-burst field-strength meter¹; (c) a noise-burst counter²².

In order to understand the structure of a lightning flash under conditions of intermediate resolution, several records of noise bursts for different periods of time during different hours of day have been obtained using the level recorder at several frequencies. A small portion of a typical record is reproduced in Fig. 1. The background is due to the set noise and other noises of the same order. In this particular case, it is equal to a signal input to the receiver which corresponds to a field strength of $0.8 \mu\text{V/m}$. The noise-burst field strengths are tens of times greater than this. The interval between the time when a burst becomes audible and the time when it ceases to be so is the duration of the burst. This corresponds to AB in Fig. 1 for the burst marked 'P'. The interval between successive audible bursts corresponds to AC in Fig. 1 for the bursts marked 'P' and 'Q'. Data thus obtained have been utilized to investigate the distribution of the duration of lightning flashes and the time interval between them.

In the noise-burst field-strength meter, the noise bursts are fed to a semi-logarithmic amplifier with a vacuum tube voltmeter which has charging and discharging time constants of 10 and 500 msec respectively. The microammeter in this output unit is calibrated by feeding signals modulated 30 per cent by a 400 c/s note from a standard signal generator to the receiver input through a capacity equal to the aerial capacity. The results are reduced to

Fig. 1. Noise bursts arising from lightning flashes as recorded on March 26, 1965, between 1600 and 1700 h I.S.T. (frequency, 3 Mc/s; bandwidth, 3.2 kc/s)

Fig. 2. Flashing characteristics as logged with 10-kc/s bandwidth, 3-Mc/s lightning flash counters. (a) Thundercloud in an overcast sky on May 4, 1962 (counter threshold, $200 \mu\text{V/m}$). (b) Isolated cloud in a clear sky on March 26, 1963 (counter threshold, $100 \mu\text{V/m}$)

equivalent field strengths in $\mu\text{V/m}$ by taking account of the effective height of the aerial. When a noise burst is received, there is a momentary kick of the pointer of the microammeter and the highest scale division it crosses is noted. This value is generally described as the quasi-peak value of the noise-burst field strength. The arithmetical average of the quasi-peak values of the ten highest noise bursts received per minute is described as the 'noise-burst level'.

The noise-burst counter, or the lightning-flash counter, is basically the noise-burst field-strength meter just described. By adjusting the sensitivity of the receiver to a predetermined threshold, it is made to pick up only the noise bursts which produce a field exceeding the threshold. The noise bursts so obtained at the detector are amplified and fed to an impulse stretcher having the same time constants as the vacuum tube voltmeter of the noise-burst field-strength meter. The output of the impulse stretcher is fed to a telephone call register which records the number of bursts received. This instrument has been used to study the variation of the rate of flashing with time.

The parameters of lightning flashes arising from a thundercloud or a thunderstorm exhibit both random and systematic variations. It is the systematic variation which reflects the growth and decay of activity. Random variations can be investigated by making the period of observation as small as possible, but this limits the available population for examining the distribution. The best compromise has been found to lie in the choice of a 5-min period. In the case of any one storm, it is found that the duration of a lightning flash, the time interval between successive flashes and the received noise-burst field-strength have a log-normal distribution. When the activity of a thundercloud is around its peak, the mean value of the duration of a flash is about 200 msec. At other times, it is larger. In the case of a frontal type of storm, the mean value of the duration is generally about 500 msec. The mean value of the noise-burst field-strength is most frequently found to be about 3 dB below the noise-burst level defined earlier.

The activity of several thunderclouds^{18,19} has been studied individually by investigating the variation of the rate of flashing with the time using the lightning-flash counter. A typical unsmoothed characteristic is shown in Fig. 2(a). A feature frequently noticed is the rather sharp fall in the activity during the decay. If the characteristics are smoothed by the method of moving averages, the real crests and troughs in the characteristics can be located. The time interval between successive crests or troughs is a measure of cell life. The cell life is found to be about the same as that reported from

Fig. 3. Storm activity as logged with a 6-kc/s bandwidth noise-burst field-strength meter at Poona at frequencies and on dates shown inside the figure. (a) Local storm over land; (b) and (c) frontal storms over land; (d) storm over the sea.

investigations at higher latitudes, namely, about 30 min. However, the mean duration of the activity of a thundercloud and the mean value of the number of cells developed during the lifetime of a thundercloud are different, namely, about 3 h and 5 respectively. The general characteristics of a thundercloud do not appear to differ with types of storm. The peak activity of a thundercloud has been observed to occur between 1400 and 0400 h L.M.T. The number of thunderclouds showing peak activity after local sunset but before midnight is the largest. A reasonable number of thunderclouds reach their peak activity during late afternoons. At other times during the day, peak activity has not been noticed so very frequently. It must be pointed out that the distribution of the hour of peak activity over the different hours of day varies with the seasons. The

mean value of the peak rate of flashing is 8 and the average value of the rate of flashing during the lifetime of a thundercloud is 3.

There is, quite often, residual activity after the collapse of an active thundercloud. This can go on for even 4 or 5 h. Flashes can be seen and these may be accompanied by thunder also; but the rate of flashing is very low, namely, of the order of one flash in 5 min. Such residual activity of several thunderclouds in a frontal storm can contribute significantly to its rate of flashing.

Whenever the activity of a thundercloud is accompanied by thunder also, there are always some ground strokes. In about 75 per cent of the cases, the activity of thunderclouds is accompanied by thunder. Examined on a long-term basis, the percentage of flashes to the ground appears to be about 10. It has so far not been found possible to distinguish ground flashes from other types of flashes by a study of noise bursts. Attempts made even at such low frequencies as 10 kc/s have been unsuccessful.

On some warm quiet days, there can be one or two isolated clouds in an otherwise perfectly clear sky and these clouds may be at very low heights. Flashes other than ground flashes have been seen in such clouds. A typical flashing characteristic is reproduced in Fig. 2(b). The rate of flashing is invariably low and the noise-burst field-strength received is about 6 dB lower than that for a corresponding thundercloud.

In the case of frontal storms, an examination of the noise data indicates the following characteristics as probable. The activity lasts several hours. During this period, the rate of flashing increases either gradually or sharply to a maximum, remains around this value for a significant period and then decreases. For the greater portion of the duration of the activity, the rate of flashing exceeds the value of 10 and can reach the value of 40; but ordinarily the maximum value is around 25.

The activity of several frontal storms¹⁸ has been followed by studying the variation with time of the noise-burst level, which can be taken as an index of the total power radiated in the form of flashes. Typical curves are reproduced in Figs. 3 and 4. Fig. 3(a) represents a type of storm frequently observed during March-May and September-November. This may be what corresponds to a local storm as observed over tropical land masses. Fig. 3(b) corresponds to the more common one after the monsoon has set in. Fig. 3(c) corresponds to a type of storm which gradually builds up and reaches peak activity a little before sunset. It has not been possible to obtain the complete characteristics of such storms but they appear to decay gradually and last until the early hours of the morning. The storms shown in Fig. 3(b) and 3(c) appear to be typical frontal storms over land. Fig. 3(d) and Fig. 4 give typical characteristics of storms over the sea. A peculiar feature of such storms is a noticeable peak around 1600-1700 h L.M.T.

If a generalization were to be attempted on the basis of the data available, it would be as follows: the activity of a frontal storm commences at about 1200 h L.M.T. In some cases, it gradually builds up to a peak before sunset.

Fig. 4. Storm over the sea as logged at Bangalore on March 19-20, 1965, at 60 kc/s with a bandwidth of 1.8 kc/s.

In others, it rises sharply after about 1600 h L.M.T. and reaches a peak after sunset but before midnight. Generally, the activity is quite significant from late evening until the early hours of the following morning. The fall in activity around the hour of local sunrise is quite sharp and probably corresponds to the collapse of the storm. The activity after midnight is significantly lower than that before midnight.

The features described follow logically from the observed characteristics of thunderclouds including the distribution of their hour of peak activity over the hours of a calendar day on the basis of the description of a frontal storm in terms of thunderclouds as given earlier. The residual activity of individual thunderclouds described previously is also one of the contributing factors.

I thank many of my students for help in various parts of this work, and Sir Basil Schonland for advice.

EFFECTS OF PRONOUNCED ELECTRON-CONTENT VARIATIONS ON DOPPLER SHIFT AT LOW ELEVATIONS

By HAIM SOICHER

Institute for Exploratory Research, U.S. Army Electronics Command, Fort Monmouth, New Jersey

THE non-relativistic Doppler shift in the ionosphere is defined as the time derivative of the optical path:

$$\Delta f = \frac{f}{c} \frac{d}{dt} \int_0^{S(p)} n_i ds \quad (1)$$

where Δf is the shift of the emitted frequency f , c is the velocity of light in free outer space, and n_i is the refractive index at the element ds of the curved ray path S , which starts at the satellite position p and terminates at receiver position 0. If we assume an isotropic, time-varying ionosphere and use the high-frequency approximation for the refractive index, equation (1) becomes¹:

$$\Delta f = \frac{f}{c} \left(1 - \frac{k N_p}{f^2} \right) \frac{dS}{dt} - \frac{k}{c} \frac{1}{f} \int_0^{S(p)} \frac{\partial N_i}{\partial t} ds \quad (2)$$

where $k = 4.03 \times 10^7$ cgs units, N_p is the electron density at the satellite, N_i is the electron density along path element ds , and $\frac{dS}{dt}$ is the component of the satellite velocity along the ray path. Equation (2) may be written²:

$$\Delta f = \frac{f}{c} \frac{dS}{dt} - \frac{k}{cf} \frac{dS}{dt} \left[N_p + \frac{1}{dS/dt} \int_0^{S(p)} \frac{\partial N_i}{\partial t} ds \right] \quad (2')$$

The first term describes the Doppler shift in the absence of the ionosphere; the second term includes contribution to the frequency shift from electrons in the vicinity of the satellite and from integrated electron-density fluctuations along the ray path. An additional interpretation of equation (2) can be made. The first term in the right-hand side of equation (2) can be thought of as the contribution of the motion of the satellite and the existence of 'static' (frozen) ionosphere to the Doppler shift. The second term may be thought of as the contribution to the shift of integrated density fluctuations assuming the satellite position is fixed.

Some anomalous Doppler curves describing satellite signal reflexions from ionospheric ionization irregularities³, traversal of the transmitting satellite from a non-illuminated ionosphere into an illuminated one during ground reception⁴, and reception of beyond-the-horizon propagation mode⁵ have been previously described in the literature. However, the anomalous (though continuous) Doppler curve of 1959 Iota I (20-Mc/s beacon frequency, inclination 50°, apogee 1,100 km, perigee 550 km), orbit No. 8274, will be shown to be an example of a large contribution to the Doppler shift from the integrated-electron-density time variations.

Generally, most Doppler irregularities occur at a period when the satellite is near the horizon with respect to the receiving station, since, at this position, the ionospheric sensitive signal has its longest path within the ionosphere, and is incident on the various ionospheric layers at rather low angles. Fig. 1 shows that the Doppler shift from 01:59 to about 240 sec afterwards deviates from the shift extrapolated from the entire observed orbital shift by a

Fig. 1. Anomalous Doppler curve of satellite 1959 Iota I, orbit No. 8274, 23 May, 1961, Δf measured with reference to an injection frequency above the shifted frequency. (Note deviation of observed Doppler curve from extrapolated dashed curve during first 240 sec of orbit reception)

maximum of 50 c/s. The extrapolation that yields the 'normal' (dashed) curve in Fig. 1 was made on the assumption that the Doppler curve is nearly symmetrical with respect to the inflexion point. The orbital zenith angle varies from 85.3° at 01:59 E.S.T. to 66.30° at 02:03 E.S.T. The zenith angles are the complements of the angles the cosines of which determine the magnitude of the component of the velocity of the satellite in the direction of the ray path. However, the foregoing angles cannot deviate sufficiently to cause an anomalous shift of 50 c/s (due to refraction effects of reflexion from ionospheric irregularities). In addition, the fact that the entire satellite reception period is within the geometric horizon of the receiving station rules out beyond-the-horizon indirect reception of the signals of the satellite-ground ionosphere mode or satellite-ionospheric irregularity-ground mode (abrupt discontinuities in Doppler curve). Further, the satellite and the ray path during the time of reception were completely in a non-illuminated ionosphere, which rules out the possibility of effects due to solar illumination of the ionosphere.

Assuming that the electron density at the satellite (N_p) would be the same for a 'normal' Doppler reception as for the anomalous one (shown in Fig. 1) during the first

4 min of reception, and that the refractive effects ($\frac{dS}{dt}$) are the same for both the normal and anomalous modes, we may arrive at a possible mechanism for the observed anomaly. Using equation (2) for the observed and 'normal' shifts, at the time of maximum frequency shift deviation, we obtain:

$$\Delta f_{\text{observed}} - \Delta f_{\text{normal}} = +50 \text{ c/s} = -\frac{k}{cf} \left[\int_{\text{observed}} \frac{\partial N_i}{\partial t} ds - \int_{\text{normal}} \frac{\partial N_i}{\partial t} ds \right] = -\frac{k}{cf} \delta \left[\int_0^{S(v)} \frac{\partial N_i}{\partial t} ds \right] \quad (3)$$

Now, because in this case the frequency deviation is a positive quantity it follows that:

$$\left[\int_{\text{observed}} \frac{\partial N_i}{\partial t} ds - \int_{\text{normal}} \frac{\partial N_i}{\partial t} ds \right]$$

is a negative quantity. The sign of the foregoing integrals is obtained from the continuity equation:

$$\frac{\partial N}{\partial t} = q - L - T$$

where q is the production of electrons term, L is the loss of electrons term and T is the transport term. At night the production term is non-existent. The integrated $L + T$ term, when one considers only vertical transport which is effective mostly at altitudes below that of the satellite, is dominated by the loss term. It follows that in this particular night orbit the integrated electron variation is dominated by the rate of disappearance of electrons due

to attachment and recombination processes and hence is negative. It further follows that:

$$\int_{\text{observed}} \frac{\partial N_i}{\partial t} ds$$

must be more negative than:

$$\int_{\text{normal}} \frac{\partial N_i}{\partial t} ds$$

in order to yield a negative difference. It is concluded, therefore, that the observed rate of loss of electrons along the path is steeper than the one normally expected. One solves for:

$$\delta \left[\int \frac{\partial N_i}{\partial t} ds \right]$$

in equation (3) and concludes that the variation of the electron-density fluctuations along the ray path during the anomalous portion of the Doppler curve is 7.5×10^{11} electrons/cm² sec. This value is an order of magnitude higher than the 'average' change in electron-content fluctuations (frequency scintillations) obtained by Arendt⁶ for data of 1959 *Iota* 1 from March 13 to August 2, 1961. However, Arendt's data, which are based on the average of the root mean square deviations (± 2.54 c/s on 20 Mc/s) of observed Doppler-shift data points with respect to a best fitting curve, do not represent an anomalous Doppler behaviour, but merely point to the uncertainty in precise frequency determination of an ionospherically passing signal.

The termination of the Doppler anomaly at 02:03 need not indicate the end of the electron-content fluctuation. It merely indicates that, with the increase in the angle between ray path and satellite, the first term in equation (2, 2') becomes dominant and the Doppler curve assumes its undisturbed shape. The electron-content fluctuations become the deviations of the observed data points from a best fitting curve. (Note scintillations between 200 and 300 sec after start of orbit in Fig. 1.) At still higher elevations the first term of equation (2, 2') becomes more dominant, and the signal is incident perpendicularly to the various ionospheric layers so that the scintillations become minimal. (Note smooth curve in the vicinity of the inflexion point.)

In conclusion, the observed Doppler anomaly at low elevation is caused by a substantial decrease of the electron density along the ray path. At higher elevation, the Doppler shift is dominated by other factors which overshadow the effects of the density enhancement.

I thank Dr. P. R. Arendt of the Institute for Exploratory Research for advice.

FRACTIONATION OF RIBONUCLEIC ACIDS IN THE ZONAL ULTRACENTRIFUGE

By DR J. R. B. HASTINGS, DR J. H. PARISH, DR K. S. KIRBY and E. S. KLUCIS

Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, Fulham Road, London, S.W.3

RIBOSOMAL RNA is recognized to have two major components of sedimentation constants about 28s and 18s when the RNA is of mammalian origin¹, while from bacteria the values are a little lower: 23s and 16s. These main components have been isolated in small quantities; but since it is clear that RNA precursors are incorporated into all classes of RNA separated by sucrose

gradient centrifugation, it is important to develop methods whereby recovery of several fractions can be achieved for investigating their physico-chemical properties and bio-synthetic potentialities. We have already shown that RNA from rat liver separated with the rapidly labelled RNA² (method 2) will stimulate the incorporation of amino-acids in a cell-free system (Wilkinson and Kirby,

to be published) and also that the patterns of mRNA on countercurrent distribution are altered: (1) by the action of hormones³, and (2) by carcinogens⁴. Differences were more readily shown by countercurrent distribution than by sucrose density gradient centrifugation.

We have recently had available the Anderson zonal ultracentrifuge⁵ and have found that the separations by sucrose density centrifugation on this instrument are better than on the Spinco model L centrifuge. A much greater quantity of material can be used and recovery at various points along the gradient is good, giving 75–85 per cent total recovery. Moreover, the material from the main peaks is undenatured as, after recovery and drying, it can be centrifuged again to the same position.

Generally, 30–80 mg RNA were dissolved in 0.1 (or 0.15 M) M NaOAc with 2.5 per cent sucrose and centrifuged in a sucrose gradient (5–20 per cent) (0.1 or 0.15 M NaOAc) at 40,000 r.p.m./6 h. The gradients have been based on our experience with separations on the Spinco model L or the M.S.E. 'Superspeed 50' centrifuges.

Fractions (40 ml.) were collected and the optical density recorded automatically at 280 m μ . Fractions were pooled as shown in the figures and RNA was recovered by making the aqueous phase about 10 per cent with respect to NaOAc at pH 6.5 and then adding 'AnalaR' acetone (about 1.5–2 vol.) until two phases are just formed. After standing at 0°/18 h RNA is precipitated in the very small volume of lower phase, from which it can be recovered, washed with ethanol, water, sodium acetate (75:25:2), pH 6.5, and dried.

The radioactive material was counted in a liquid scintillation counter. After suitably diluting an aliquot of the fraction from the sucrose gradient with water so that [Na⁺] was 0.05 M or less, a mixture of butanol, diethyl-dihexylamine and acetic acid was added which extracted all the RNA into the organic phase and this was added directly to the scintillation fluid for counting.

RNA from rat liver. Fig. 1 shows the optical density and radioactive pattern of RNA (34 mg) isolated from rat liver² (method 2) 20 min after injecting 200 μ c. orotic acid/rat. Five fractions were recovered as indicated on the diagram with a total recovery of 85 per cent. The RNA suffered no denaturation or degradation in the density gradient centrifugation or in the process of recovery and drying since dissolution of fraction 1 and of fraction 3 and centrifuging these materials again on sucrose density gradients showed that these fractions corresponded exactly with the 18s and 28s components (Fig. 2). The material from fraction 2 was not a mixture of these components but always contained material of intermediate sedimentation values (Fig. 3). A small additional peak or shoulder in the optical density pattern of the unfractionated material was occasionally observed in the trough between 18s and 28s. The fraction of highest sedimentation values (fraction 5) contained some

28s and 18s and the nature of this material will be considered in the fractionation of the rRNA from *E. coli*.

In each case when a fraction was dissolved and re-centrifuged on the Spinco model L centrifuge a sample of the original, unfractionated material was centrifuged at the same time. The optical density pattern of this material is included in the same graph on which the optical density and radioactive patterns of the various fractions have been drawn.

Previous experiments have shown that hormones and carcinogens can alter the pattern of rapidly labelled RNA isolated from liver after injection of tritiated orotic acid. The changes in patterns were marked in comparisons made by countercurrent distribution but much less by centrifugation in sucrose density gradients. Because of the improved resolution of ribosomal RNA in optical density patterns we have investigated the separation of rapidly labelled RNA in sucrose density gradients by the zonal ultracentrifuge. Fig. 4 shows the optical density and radioactive patterns of RNA from livers of rats which had been on a diet of thioacetamide⁶ for 31 weeks, while Fig. 5 shows those of RNA extracted from liver 60 min after an injection of insulin (20 units/rat). The results confirm the previous experiments, which indicated that the pattern of rapidly labelled RNA was altered by feeding 4-fluoro-4'-dimethylaminoazobenzene (a liver carcinogen) for a protracted period and by various hor-

mones after relatively short periods. The present method has the advantage that good recoveries make several other investigations possible.

RNA from *E. coli* was isolated from bacteria in the exponential growth phase by extraction with 4-amino-salicylate, triisopropyl-naphthalene sulphonate and a phenol/cresol mixture. RNA was recovered after precipitating DNA with *m*-cresol (method to be published). The material used consisted of 40 mg unlabelled RNA and 5 mg of RNA which had been labelled for 20 sec with tritiated uridine. The optical density patterns of the labelled and unlabelled RNA, centrifuged separately on the Spenco model L centrifuge, were previously shown to be identical. Fig. 6 shows the radioactive and optical density patterns and the mode of fractionation of this material. The recoveries in Table 1 may be compared with those from rat liver RNA. It should be noted that RNA can be effectively recovered even when present in minimal concentration in a region of the sucrose gradient.

	5	1,280-1,480	2.5
	Combined recovery = 85 per cent		

Re-centrifugation of fractions 3 and 5 showed that these were almost pure 16s and 23s components and the radioactive pattern followed the optical density pattern almost exactly. Fraction 4, from the trough between the two ribosomal RNA peaks, differed from the corresponding fraction from rat liver RNA in that the optical density pattern showed the major component to be 16s RNA with a small amount of 23s RNA also present (Fig. 7). The radioactivity followed a similar pattern but was displaced to the heavy side of the optical density pattern. An analogous material was obtained from fraction 6, except that the major component was 23s RNA; the radioactive material again appeared on the heavy side of the optical density pattern.

Fractions 1 and 2 were of interest as they contained a considerable amount of RNA of high specific activity, which was present in two main fractions (A and B). Monier *et al.*⁷ have also reported material of high specific activity from *E. coli* in the 16s-4s region.

The pattern obtained by centrifuging the RNA from fraction 2 is shown in Fig. 8. It will be noted that the optical density pattern is composite and contains some 16s RNA in addition to other lighter components. The radioactive pattern shows that at least three components are present (if the 4s RNA is included). As the radioactive pattern of the 16s RNA from fraction 3 follows almost exactly that of the optical density, composite curves have been included in Fig. 8 on the assumption that the relative specific activity of the 16s and 4s RNAs was 1 and that of components A and B was 6. The curves are good evidence for the presence of these two components of this relative specific activity. Further support was

Fig. 6. RNA from *E. coli*. 45 mg dissolved initially in 40 ml. of 0.15 M sodium acetate pH 6.5/2.5 per cent w/v sucrose/1.5 h/2° C. Samples dissolved in 0.15 M sodium acetate/1.5 h/2° C and centrifuged (5-20 per cent w/v sucrose gradients) on Spenco model L, S W. 25 for 14 h/25,000 r.p.m./4° C. —, Unfractionated RNA (0.8 mg), optical density; - - - - -, fraction 4 (0.4 mg), optical density; ·····, fraction 4, c.p.m. Direction of centrifugation: right to left

obtained by similarly analysing the patterns obtained by centrifugation of fraction 1 (Fig. 9). It will be seen that this fraction contains only a small amount of component B and the bulk of component A is present in fraction 1. It is of considerable significance that, in addition to detecting components A and B by radioactivity, their presence is quite clear from the composite optical density tracings.

The RNA from fraction 7 probably corresponds to the rat liver RNA fraction 5. The re-centrifugation of the *E. coli* material is shown in Fig. 10. It will be noted that the pattern obtained depends on the temperature of dissolution of the fraction. The ratio of the absorbance 260 m μ /absorbance 280 m μ was 2.15 for fraction 7 and

also for material at the heavy peak ($\sim 35s$) after re-sedimenting. It is most unlikely then that any protein is present. Since the material gives a greater proportion of components corresponding exactly to the 23s and 16s RNA on dissolution at a higher temperature, it is possible that this heavy fraction (35–40s) may be a deproteinized ribosome and the high specific activity associated with it may indicate that mRNA (or segments of mRNA) also remains bound to this 'skeleton'. Mammalian RNA from the fraction 5 region (Fig. 1) showed a similar tendency to dissociate on redissolution into material sedimenting principally at 18s and 28s.

It is possible then that one factor in the association of the 30s and 50s ribosomal segments could be complementary sequences on the 23s (or 28s) and 16s (or 18s) RNAs, but further work will be required to clarify this point.

Ishihama *et al.*⁸ were able to separate three significant fractions of rapidly labelled RNA from *E. coli* by chromatography on a column of methylated albumin-kieselguhr. Their fraction IV had a peak about 35s on centrifugation in a sucrose gradient and is possibly the same as our fraction 7 (*E. coli*). This fraction was absent when the cells were grown in the presence of chloramphenicol, and it was suggested that the antibiotic may have inhibited the biosynthesis of fraction IV. We would suggest that in the absence of protein biosynthesis incomplete ribosomes (chloramphenicol particles⁹) are made and, in this condition, are unable to bind rapidly labelled RNA (mRNA). Their fractions II and III are not identical to ours but, judging from their sedimentation on gradient centrifugation, are equivalent to part of our fractions 1 + 2 and 2 + 4, respectively.

Scherrer and Darnell¹⁰ and Steele, Okamura and Busch¹¹ have also demonstrated the presence of RNA sedimenting about 35s–45s. Darnell *et al.*¹² were of the opinion that their material from HeLa cells was mainly ribosomal precursor: it had a base composition similar to that of ribosomal RNA and showed only a small degree of hybridization with DNA. It should be noted that after isolating the RNA from HeLa cell polysomes the material with highest specific activity was in the 4s–18s region of the gradient. In addition to 35s material faster sedimenting RNA was present in the extracts from HeLa cells¹⁰ and liver⁹ and, on the analogy that the 35s fraction is 28s + 18s RNA + mRNA, it is possible this 45s fraction consists of deproteinized polysomes.

It is certain therefore that, in addition to the separation of the main components, other fractions of RNA, some of which may be composite, can be isolated by this method, although further characterizations are required to clarify the relationships of the components.

The success of the present method is dependent on the stability of our RNA preparations (in no instance is bentonite required to prevent degradation) and on the ability of the zonal ultracentrifuge to deal with great quantities of RNA and yield better resolution than the standard sucrose density centrifugation.

We thank Prof. A. Haddow for his interest, Dr. N. G. Anderson for making the zonal ultracentrifuge available, and Dr. P. Alexander for co-operation in its use. We also thank Mr. E. A. Cook and Mrs. E. L. Fox-Carter for their assistance, and the Medical Research Council for a grant in support of this work.

EFFECT OF STEROIDS AND 'TRITON X-100' ON GLUCOSE-FILLED PHOSPHOLIPID/CHOLESTEROL STRUCTURES

By DR. GERALD WEISSMANN, DR. GRAZIA SESSA and DR. SIEGMUND WEISSMANN

Department of Medicine, New York University School of Medicine, and Materials Research Laboratory, College of Engineering, Rutgers, The State University, New Brunswick, New Jersey

IT has previously been reported that pharmacologically active steroids affect the membranes of lysosomes, mitochondria, and erythrocytes¹⁻⁵. In each of these systems, steroids such as deoxycorticosterone (DOC), etiocholanolone, or progesterone, which do not possess oxygen functions in the 11 or 17 position, appear to disrupt the surfaces of cells or their organelles. In direct contrast, cortisol, cortisone, and their acetates appear to protect membrane-bounded structures against disruption by a variety of agents. Because this property of steroids might account, at least in part, for their pharmacological or physiological activity, the interaction of steroids with lipids common to several biological membranes was examined.

Bangham, Standish and Watkins⁶ have shown that purified phospholipids swell spontaneously in aqueous salt solutions to form liquid crystals, which behave as salt-containing compartments limited by discrete membranes. Such structures appeared as spherulites composed of concentric lamellae, each of which assumed the configuration of a bimolecular leaflet. The spherulites were shown to exhibit permeability characteristics for simple univalent cations, anions, and water, which were qualitatively similar to those occurring across biological membranes. Utilizing such artificial phospholipid structures, we have previously shown that steroids which disrupt lysosomes and other membrane-bounded bodies increase the leakage of trapped cations from their model counterparts⁷. Furthermore, cortisone, cortisol, and their acetates appeared to retard leakage of cations from the artificial structures. Other membrane-disruptive agents such as 'Streptolysin S' and lysolecithin also increased leakage of cations from the spherulites; negatively stained preparations of streptolysin- or lysolecithin-treated spherulites showed that the concentric lamellae had been visibly disrupted⁷.

This report indicates that glucose, like small anions and cations, may be sequestered within artificial phospholipid/cholesterol spherulites, and that membrane-active steroids can modify the permeability of these structures to glucose. Such functional alterations were accompanied by drastic changes in the morphology of the spherulites, viewed by negative-staining techniques in the electron microscope. The action of steroids on these model structures will be

contrasted with changes induced by a non-ionic detergent 'Triton X-100', an alkylphenoxo, poly-ethoxy, surfactant which has previously been shown capable of totally disrupting lysosomes, mitochondria, and erythrocytes¹⁻⁴.

The phospholipid/cholesterol structures, carrying a net negative membrane charge imposed by the anion dicetylphosphate, were prepared by a modification of procedures described in detail elsewhere^{6,7}. Ovolecithin was obtained from General Biochemicals, Chagrin Falls, Ohio, eluted from silicic acid columns in chloroform, and was shown to be free of trace contaminants by thin-layer chromatography. Cholesterol was obtained from Nutritional Biochemicals, Cleveland, Ohio, dicetylphosphate from K and K Biochemicals, Plainview, New York, and steroids obtained from Steraloids, Inc., Pawling, New York. 'Triton X-100' was the gift of Rohm and Haas, Philadelphia, and 'Streptolysin S' of Dr. A. W. Berheimer, New York University.

For each set of experiments, 60 μ moles of ovolecithin, 17.16 μ moles of DCP, and 8.58 μ moles of cholesterol were added in chloroform to a 100-ml. round-bottomed flask. The contents were evaporated in a rotary vacuum-pump apparatus so that the dried lipid was evenly distributed over the lower surface of the vessel. Finally, 6 ml. of glucose solution (0.145 M) were added to the flask, and the lipids were dispersed in the aqueous medium by anchoring the covered flask in contact with a vibrating mixer ('Cyclo-mixer', Clay-Adams Co., New York City) so that small drops of the dispersion were constantly thrown against the side of the flask during vibration (10 min, 23°C). Thereafter, the lipid structures were permitted to complete their spontaneous swelling for 18 h at 4°C. After a second period of vibration (5 min), the lipid particles, which were suspended in aqueous glucose, but now also containing glucose that had been sequestered within lipid lamellae, were placed into Visking dialysis tubing. They were first dialysed for 30 min at 23°C against 900 ml. of an equimolar mixture of NaCl/KCl (total molarity 0.145 M), and dialysis was continued against fresh salt solution until the last dialysate was free of detectable glucose. Usually four, hourly, changes of 900 ml. each were sufficient. One-ml. portions of the dialysed spherulites, now containing only that glucose which had been sequestered, were placed into five.

separate, small dialysis sacs. Test steroids, dissolved in 0.05 ml. of ethanol, or 0.05 ml. of ethanol alone, were dispensed into the sacs and immediately mixed with the suspended spherulites by inversion. To some suspensions, 0.2 ml. of 'Triton X-100' in NaCl/KCl was added to a final concentration of 0.1 per cent v/v. 'Streptolysin S' was dissolved in 0.1 ml. of NaCl/KCl. The sacs were tied, placed into small, narrow-bore test-tubes containing 5 ml. of NaCl/KCl solution, and shaken in a water bath maintained at 37° C. At intervals noted below, the sacs were transferred to fresh test-tubes also filled with NaCl/KCl and the glucose which had escaped through the dialysis casing from the spherulites during these 'leak' periods was determined. After each experiment, aliquots, each of 900-ml. dialysate, of the 'leak' fluids, and of the suspension remaining in the sacs, were analysed for glucose by the glucose oxidase method⁸ ('Glucostat', Worthington Biochemicals, Freehold, New Jersey). Suspensions remaining in the sacs were, however, first boiled for 20 min to destroy the spherulites, centrifuged at 20,000g to remove lipid debris, and the clear supernatants were analysed. In six sets of experiments, total recoveries of added glucose ranged from 98 to 107 per cent. An average of 43.8 per cent of added glucose was trapped within the spherulites after the last 900-ml. dialysis; therefore for 10 μ moles of phospholipid (present in each test suspension) approximately 80 μ moles of glucose were sequestered within the structures.

In Table 1 are shown the results of experiments in which 5-mM concentrations of steroids altered the leakage of glucose from the lipid spherulites. DOC, etiocholanolone, and progesterone, which disrupt naturally occurring membranes (lysosomes, mitochondria, erythrocytes) augmented the leakage of glucose. In contrast, cortisol acetate, which appears to protect biological membranes, diminished the release of glucose from the model structures. In no case did leakage induced by the steroids approach that induced by the non-ionic detergent, 'Triton X-100', which totally disrupts natural membranes. 'Streptolysin S', a bacterial product which lyses cells or their organelles⁹, induced leakage of glucose to roughly the same extent as did the steroids. Fig. 1 shows that leakage was progressive with time, and shows that etiocholanolone-induced release of glucose was relatively delayed compared to DOC, a finding that has since been confirmed for other marker molecules such as phosphate, chromate, and glycine¹⁰.

In an extension of these findings, to be reported in detail elsewhere¹⁰, we have tested the possibility that the interaction of steroids with lipid-bounded structures might regulate enzyme action. Glucose-laden phospholipid cholesterol spherulites were placed in dialysis sacs as stated. However, the sacs were allowed to 'leak' into test-tubes containing not only 0.145 M NaCl/KCl solution, but also the enzymes glucose oxidase, peroxidase, and chromogen. Accelerated formation of reaction product (compared to controls) was seen in tubes with sacs of spherulites to which 'Triton', DOC, or etiocholanolone had been added, as the medium became coloured by chromogen. Tubes to which cortisol acetate had been added showed a delay in the development of colour. These experiments indicated

Fig. 1. Release of glucose from artificial phospholipid/cholesterol structures. Results expressed as percentage released from control suspensions at 30 min (10.9 μ moles/ml. suspension). Steroids added at 5 mM concentration, 'Triton X-100' 0.1 per cent v/v

that steroids might regulate enzyme action by modifying the rate at which substrate was made available to the enzyme.

However suggestive these functional studies might be, it was still possible that steroids influenced the attachment or binding of glucose to the lipid membranes, without actually altering their structure or spatial disposition. Therefore the spherulites were studied by negative-staining techniques in the electron microscope in order to identify any possible morphological consequences of steroid action. Aliquots of the spherulite suspensions, prepared as already described, but before dialysis, were exposed to steroids or 'Triton X-100' for 20 min at 23° C. They were kept at 4° C for 3 h (to permit transport), mixed with an equal volume of 3 per cent phosphotungstic acid, and sprayed on a carbon-coated grid by means of an ordinary nebulizer. They were examined in a Hitachi HU 11A electron microscope. Fig. 2a shows a negatively stained preparation of the phospholipid/cholesterol structures, incubated in the presence of ethanol alone. The majority of the figures appeared as spherulites, spread out on the grid, and frequently superimposed on each other. Most measured between 0.2 and 0.8 μ in diameter, although larger, composite figures were occasionally observed. Each spherulite, in appropriate specimens, appeared to be composed of concentric lamellae, usually at a distance of 45–55 Å between layers. Therefore these structures resemble those previously described by Bangham, Standish and Weissmann, with the important difference that the spherulites prepared with 0.45 M glucose are much more discrete, and show considerably less coalescence than did the structures previously described, which were prepared in water. To exclude *moiré* effects as the source for the lamellar appearance, specimens were tilted in the electron beam, but this had no effect on the concentric, lamellar appearance.

When the specimens were incubated with 'Triton X-100', their distinct spherular organization was entirely lost, no lamellar structure could be identified, and the grids appeared filled with deposits of amorphous material (Fig. 2b). However, in contrast to these and to controls, samples which had been incubated with 5 mM DOC showed the emergence of entirely new forms. Although smaller, discrete spherulites could still be identified, the predominant forms were a series of frayed, strand-like structures, loops and swirls of which maintained a lamellar sub-structure (Fig. 2c). These strands were frequently

Table 1

Agent added	No. of expts.	μ moles	Glucose released, Per cent of controls * at 30' \pm S.E.M.
Control	6	18.1	166.3 \pm 5.5
'Triton X-100'	6	30.7	281.0 \pm 27.9
DOC	4	25.5	234.5 \pm 10.9

Progesterone	4	21.0	193.5 \pm 14.1
Cortisol acetate	3	16.8	154.3 \pm 5.7
'Streptolysin S'	2	21.9	201.0

* Control tubes leaked 10.9 μ moles in 30 min. Release of glucose from phospholipid/cholesterol structures. See text for detail of preparation of lipid spherulites composed of o-oleic acid/cholesterol/dicetylphosphate (70:10:20). Each ml. of spherulite suspension sequestered an average of 80 μ moles of glucose before steroids (5 mM), 'Triton X-100' (0.1 per cent v/v) or streptolysin (2,000 haemolytic units) was added. Solvent controls were 0.05 ethanol for steroids, 0.1 ml. NaCl/KCl (0.145 M) in other tubes. Leakage measured after 60 min at 37° C.

Fig. 2. *a*, Electron micrograph of artificial phospholipid/cholesterol structures. See text for preparation of these spherulites, which have been prepared in 0.145 M glucose and negatively stained with 3 per cent phosphotungstic acid; *b*, preparation as in *2a*, but treated for 20 min at 23°C with 0.1 per cent 'Triton X-100'; *c*, preparation as in *2a*, but treated for 20 min at 23°C with 5 mM DOC (deoxycorticosterone) (\times c. 23,000)

observed as a double- or triple-layered system, sometimes tubular, which in areas appeared to merge with the outermost layers of the native structures. The distance between lamellae was still maintained at approximately 50 Å, but in some three-layered strands a middle, thicker, layer appeared which was somewhat amorphous. Longer exposure to the steroid produced a series of frayed strands and flat sheets.

Negative-staining techniques have previously been used to demonstrate the effects of other membrane-active agents on purified lipid mixtures. Saponin was shown to interact with lecithin/cholesterol dispersions so as to produce a series of new, morphologically distinct forms which could be explained by postulating the interaction of saponin with individual components of the lipid mixture^{11,12}. Lysolecithin and 'Streptolysin S' also brought about morphological changes in phospholipid/cholesterol structures; these differed from those induced by saponin. No new forms appeared, but the net effect was a sort of progressive emulsification: new channels appeared between the internal lamellae of the structures and the surrounding medium⁷. In contrast to lysolecithin or 'Streptolysin', DOC appears to have interacted with phospholipid/cholesterol structures to produce new, strand-like forms at the expense of the spherular arrangement ordinarily preferred by the lipids in 0.145 M glucose. However, because negative-staining techniques do not necessarily show the precise configuration that lipids assume in aqueous dispersion, the extrapolation of these observations to wet states, or to biological systems, is hazardous¹³. Nevertheless, the experiments strongly suggest that steroid-induced changes in the permeability to glucose of phospholipid/cholesterol spherulites are the functional expression of a physical interaction between steroid and membrane lipid. The nature of such an interaction is, at present, only conjectural. Taylor and Haydon¹⁴, testing Willmer's suggestion that steroids, as amphipathic or 'rogue' molecules, might enter into the lipid phase which bounds cells or their organelles¹⁵, found that progesterone entered into phospholipid/cholesterol films at an air-water interface. Since only small amounts of progesterone did, in fact, enter the layers, they were unable to determine whether progesterone inserted vertically, with one polar group at the interface, or, horizontally, with both polar groups at the interface. Munck previously had shown that steroids oriented horizontally at a heptane/water interface¹⁶.

Whatever the position of steroids in lipid membranes proves to be, it would appear that the presence of polar groups at C 11 or C 17 of the sterol radically alters the functional properties of biological membranes exposed to such rogue molecules. Oxygen functions at these positions considerably diminish the lytic effects of DOC, progesterone, and etiocholanolone on lysosomes, mitochondria, and erythrocytes²⁻⁵. Another structural feature is

important in determining membrane action; etiocholanolone and other 5 β -H steroids, the A : B ring junction of which is *cis*, disrupt lysosomes and erythrocytes. In contrast, the planar 5 α -H isomers of these steroids are relatively inert in membrane activity²⁻⁵. Studies with lipid spherulites filled with Na⁺ and K⁺ have shown that these structural 'rules' hold for the model system used here as well. Such observations fit remarkably with the early observations of Selye on the anaesthetic properties of steroids¹⁷. He, too, found that oxygen functions at C 11 or C 17 abolished the anaesthetic effects of etiocholanolone or progesterone, and that 5 α -H isomers were non-anaesthetic. This concordance would support theories of anaesthesia based on the capacity of anaesthetics to enter lipid membranes¹⁸; Bangham has recently found that several local anaesthetics alter the leakage rates of cations from lipid spherulites¹⁹.

We have previously reported that pre-incorporation into lipid spherulites of as little as 1 per cent cortisone, before swelling in salt solutions, produced structures that leaked cations to a lesser extent than did control spherulites on subsequent exposure to lytic agents. It is, therefore, possible that small amounts of steroids may alter the permeability of biological membranes by virtue of their insertion as rogue molecules in bimolecular lipid leaflets. The presence, in an aqueous phase, of a functional protein has been considered an integral feature of biological membranes²⁰. The investigations described here would suggest that at least some membrane phenomena may be explained without considering this protein as more than a coating for a lipid skeleton, the integrity of which may be regulated by amphipathic molecules such as steroids.

DISTINCTION BETWEEN THE EFFECTS OF ANTIVIRAL AND ANTICELLULAR POLYOMA ANTIBODIES ON POLYOMA TUMOUR CELLS

By INGEGERD HELLSTRÖM

Institute for Tumour Biology, Karolinska Institutet Medical School, Stockholm

SJÖGREN, Hellström and Klein¹ and, independently, Habel², reported in 1961 that mice immunized with polyoma virus as adults were resistant to transplantation with polyoma tumour cells. They attributed this to the presence in polyoma tumours of specific antigens determined by the virus. Sjögren later showed that mice immunized with polyoma tumour cells were also resistant to transplantation of polyoma tumours³. Resistance was also demonstrated in mice immunized with polyoma tumour clones which could not release polyoma virus particles⁴. It was hypothesized that polyoma tumour cells contain an antigen, determined by the polyoma virus but distinct from the antigen of the virus particles⁴.

It was recently demonstrated by Hellström and Sjögren that specific antigenicity of polyoma tumour cells can be detected by an *in vitro* technique in which target cells are incubated with specific isoantibodies and complement and plating efficiency then measured⁵. This method was used for the experiments to be reported. They were performed to distinguish between the effect on polyoma tumour cells of antibodies prepared respectively against the polyoma virus and the hypothetical specific polyoma tumour antigen. The tumour line used for this study, YAA-CI-C3, is a clone derived from YAA-CI, which is a sub-line of the Moloney-virus-induced YAA lymphoma of A/Sn origin that has been subjected to repeated infections with polyoma virus *in vitro* and has acquired the polyoma specific transplantation antigen^{5,6}. It was chosen because of its high sensitivity to antibodies and complement in the test system used. In a control experiment, a YAA-CI line was used which had not yet acquired the polyoma antigen. All the tumour lines tested also contain the Moloney specific antigen⁶.

Two types of anti-polyoma serum were used (Table 1): serum pools obtained from mice immunized with polyoma virus preparations as adults, and pools of 'anti-cellular-antigen' serum, derived from mice which had been inoculated with allogeneic tumours, containing the polyoma transplantation antigen but not releasing detectable polyoma virus particles. Sera obtained from mice

immunized with polyoma virus preparations all contained high levels of anti-polyoma virus antibodies which were detected both by a haemagglutination inhibition technique⁷, and by neutralization of plaque formation by the virus^{8,9}. Sera derived from mice immunized with the polyoma tumour cells did not have detectable antibodies directed against polyoma virus. In addition an A.SW anti-A serum and an A anti-A.SW serum were used. The former was a positive control because of its ability to react with the H-2^a determined antigens of the tumour cells tested. The latter was a negative control, incapable of reaction with the tumour cells.

Trypsinized cell suspensions of transplanted tumours were explanted, propagated approximately 30 days *in vitro*, and used for plating experiments, performed as previously described⁵. These cells were suspended and diluted to a concentration of 4,000 cells/0.1 ml., in conditioned Eagle's medium with 40 per cent foetal calf serum. The use of conditioned medium gathered from YAA-CI-C3 cultures 3-4 days after seeding was found to increase plating efficiency approximately tenfold. Each diluted tumour suspension was added to a tube containing 0.1 ml. undiluted antiserum and mixtures of cells and serum were incubated at 37° C for 20 min with repeated shaking. Then 0.8 ml. undiluted guinea-pig complement was added, and 60 min later 15 ml. of Eagle's medium with 40 per cent foetal calf serum was added. 4-ml. portions were plated in each of three Falcon 50-mm Petri dishes. Some experiments were made with doubled amounts of cells and sera in order to obtain sufficient material for plating in 6 Petri dishes. The dishes were incubated for 7 days at 37° C in a 5 per cent carbon dioxide-air atmosphere and stained with crystal violet, after which the number of colonies was counted.

The findings are presented in Table 2. Treatment of the tumours with A.SW anti-A serum and complement reduced the number of colonies formed after plating by 84-100 per cent, as compared with control groups exposed to an anti-A.SW serum, unable to react against the target cells. Sera from mice immunized against the

* Mice were immunized as adults by giving them one injection with a high titred polyoma virus, in order to produce antiviral sera. Serum pool 1365 was taken from mice immunized with polyoma virus as adults and given 4 inoculations with the non-releasing polyoma tumour clone SEWA-C10 (ref. 4). Antisera directed against the 'polyoma-cell-antigen' were taken from mice, given 4-8 inoculations of the non-releasing SEWA-C10 polyoma tumour clone (of A.SW origin).

† Plaque tests were performed as described elsewhere (ref. 9). Two different dilutions of a virus-containing tissue culture fluid were treated with antiserum and the reduction in plaque number was observed.

‡ Serum titres were determined according to the HI technique of Eddy *et al.* (ref. 7). Titres of up to 1:100 were considered to depend on non-specific inhibition (ref. 4), and titres of 1:200 or more clearly positive.

hypothetical polyoma-tumour antigen reduced colony numbers by 30–60 per cent although these sera did not contain detectable antiviral antibodies. Complement was necessary for reduction of plating efficiency. The antiviral sera reduced colony numbers only in some experiments. One test was performed with a line of YAA-CI which had not yet acquired detectable polyoma-induced transplantation antigenicity. It was resistant to the action of both anti-cellular and anti-viral polyoma sera but was killed by the A.SW anti-A serum.

These experiments established that the tumour line tested, YAA-CI-C3, containing the polyoma-induced transplantation antigen⁶, is sensitive to treatment *in vitro* with isoantisera directed against polyoma tumour cells but not containing detectable antiviral antibodies. Plating efficiency was only infrequently reduced by strong antiviral sera. The reduction obtained with these sera is probably due to their content of antibodies against cellular polyoma antigen(s) since the virus-immunized mice are resistant to syngeneic polyoma-tumour grafts¹.

The findings reported strongly indicate that transplantation resistance to polyoma tumour cells depends on the presence in the tumours of a new cellular antigen which is induced by polyoma virus, but differs from the antigen of polyoma virus particles.

INTERSPECIES DIFFERENCES IN RESPONSE TO POLYPEPTIDES AS PERMEABILITY FACTORS

By DR. JEAN CARR and PROF. D. L. WILHELM

Prince Henry Hospital, and School of Pathology, University of New South Wales, Sydney

THE ability of bradykinin to induce vasodilatation, increased vascular permeability and leucocytic diapedesis has directed attention to its possible function as a mediator of the early vascular events in inflammation¹. As a permeability factor, bradykinin has outstanding activity in the guinea-pig, being about 80 times more potent in this species than histamine^{2,3}. In the rat, on the other hand, bradykinin and histamine both have relatively low potency², whereas histamine has high activity in the rabbit, comparable to that in the guinea-pig⁴. To our knowledge, however, bradykinin has not been tested in the rabbit.

Bradykinin is a nonapeptide^{5,6} (Fig. 1) to which kallidin is closely related⁶; it differs only in possessing an N-terminal lysine group⁷, thus making kallidin a decapeptide. Although kallidin has pharmacological properties similar to those of bradykinin, there is little evidence concerning the relative potency of the two preparations as permeability factors. Serum kallikrein has a similar potency to bradykinin in the guinea-pig⁸, but the permeability effects of kallikrein may be mainly due to the production of bradykinin⁹.

In the present work, the permeability-increasing potency of synthetic bradykinin, kallidin and elodeisin

has been compared in the skin of guinea-pigs, rats and rabbits. This was done to assess the permeability effects of bradykinin in the rabbit, relative to its known activity in the guinea-pig and rat, to determine the relative potency of bradykinin and kallidin in all three species, and to compare the potency of an unrelated peptide, elodeisin, since the pharmacological activity of polypeptides appears to be affected both by the internal arrangements of their amino-acid residues¹⁰ and their chain-length^{11,12}. Elodeisin is a peptide¹³ containing eleven amino-acid residues (Fig. 1) obtained from the posterior salivary gland of the *Eledone*, a close relative of the genus *Octopus*.

The test preparations were injected intradermally in guinea-pigs, rats and rabbits with Evans blue circulating in their blood, according to the technique of Miles and

Bradykinin

Arg-Pro-Gly-Phe-Ser-Pro-Phe-Arg

Kallidin

Lys-Arg-Pro-Gly-Phe-Ser-Pro-Phe-Arg

Elodeisin

Pyr*-Pro-Ser-Lys-Asp(OH)-Ala-Phe-Ileu-Gly-Leu-Met-NH₂

*Pyr = Pyroglutamyl.

Fig. 1. Structure of bradykinin, kallidin and elodeisin

Miles¹⁴ and Wilhelm *et al.*¹⁵. Twenty min after completing the injections, the animals were killed and the lesions at the test sites were measured on both the upper and under surfaces of the skin. The sites were then excised and their content of exuded dye was determined by homogenizing the skin and extracting the dye by the technique of Clausen and Lifson^{8,16}. The results are recorded in Fig. 2.

Previous work³ in the guinea-pig has indicated that the potency of various permeability factors differs considerably when lesion-diameter is measured on the upper or lower surface of the skin. The procedure of dye extraction is rather tedious as a routine technique, but the results agree more closely with those obtained by measuring lesion diameter on the under rather than the upper surface of the skin².

Although the three polypeptides which were tested each evoke satisfactory responses on both the upper and under surface of rats' skin, the amounts of extracted dye are much less than in the guinea-pig, and the dosage response lines correspondingly unsatisfactory for the evaluation of relative potency. Nevertheless, our dye extraction results for the rat agree with those of other workers^{19,20} using trypan blue as a marker substance in the investigation of the permeability effects of histamine and kallikrein.

In the rabbit, on the other hand, the lesions are not estimable on the upper surface of the skin. The exudation of the dye is confined to the upper layers of the skin and does not extend down to the panniculus carnosus, which in turn is too opaque for the pale overlying lesions to be viewed from the under surface. That the amount of exuded dye is relatively small in the rabbit is confirmed by the dye extraction results (Fig. 2).

As Fig. 2 also illustrates, the amount of exuded dye in the rabbit was even less than in the rat, and the corresponding dosage-response lines were unsatisfactory for the estimation of relative potency of permeability factors.

The foregoing disadvantages in the rat and rabbit were unexpected, particularly in the latter, and hence the interspecies comparison of the three test peptides had to be confined to the results from the upper-surface readings. The outstanding activity of bradykinin in the guinea-pig and its lower activity in the rat are confirmed. In the rabbit, bradykinin has high activity, of the same order as in the guinea-pig. Relative to histamine, bradykinin has a potency of 86 in the guinea-pig and 63 in the rabbit; and relative to 5-hydroxytryptamine, a potency of 0.6 in the rat.

In all three species, kallidin has slightly less activity than bradykinin, but the relative factor is only about 1.3 in the guinea-pig, 2 in the rat, and 3 in the rabbit.

The results for eleodoisin are surprising in that this peptide has high potency in both the guinea-pig and rat, but negligible activity in the rabbit. In the guinea-pig, the activity of eleodoisin is comparable to that of both bradykinin and kallidin, but in the rat it far outstrips any factor we have tested, being 18 times more active than bradykinin and 10 times more active than 5-hydroxytryptamine.

Our results, therefore, indicate that bradykinin has high permeability-increasing activity in the rabbit, as in the guinea-pig and rat, and that in all three species its activity slightly but consistently exceeds that of kallidin. On the other hand, eleodoisin, an unrelated peptide of similar chain-length, has comparable activity in the guinea-pig, outstanding effects in the rat, but negligible

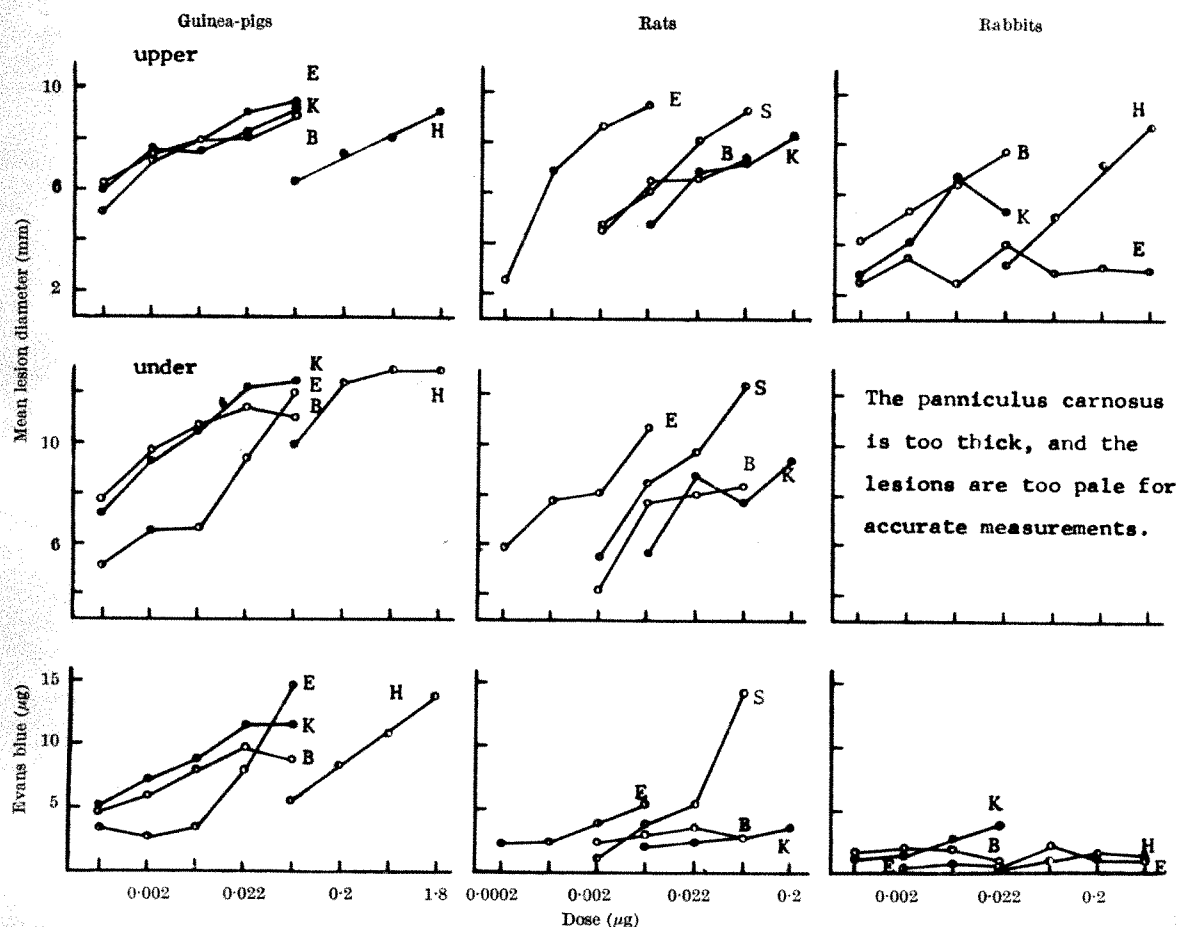

Fig. 2. Permeability-increasing potency of bradykinin (B), kallidin (K) and eleodoisin (E), relative to histamine (H), in guinea-pigs and rabbits, and to 5-hydroxytryptamine (S) in rats. The response lines record the mean lesion diameters on the upper and under surfaces of the skin, and the mean amounts of Evans blue extracted from the same lesions.

potency in the rabbit. Whatever the explanation of this unexpected result with eleodoisin, it seems noteworthy that this is still another example of a biological substance exhibiting wide variations in permeability effects according to the species of test animal³.

We thank Sandoz, Ltd., for supplies of the synthetic peptides, and the Bushells Trust for financial support to one of the authors (J. C.).

A SIMPLE BIOASSAY FOR ANTIOXIDANTS BASED ON PROTECTION OF *Tetrahymena pyriformis* FROM THE PHOTODYNAMIC TOXICITY OF BENZO(a)PYRENE

By DR. SAMUEL S. EPSTEIN, INNA B. SAPOROSCHETZ, MYRA SMALL, WELDON PARK and NATHAN MANTEL

From the Laboratories of Carcinogenesis and Histology, The Children's Cancer Research Foundation, and the Department of Pathology, Harvard Medical School, at the Children's Hospital, Boston, Massachusetts, and the Biometry Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

ANTIOXIDANTS are widely used in food, as well as in other natural or synthetic products such as petroleum, rubber and paints, to inhibit autoxidative deterioration. This subject has been well reviewed in recent publications^{1,2}. While a voluminous literature exists on chemical tests for antioxidants, biological data on their *in vivo* activity, perforce, have been restricted to some studies on vitamin E biopotency³. The present article describes a simple and rapid biological method for the *in vivo* characterization and assay of antioxidant activity based on the inhibition of the oxygen-dependent phenomenon, photodynamic injury⁴⁻⁷. This approach was stimulated by the finding that vitamin E protects a ciliated protozoan against the photodynamic effects of a polycyclic photosensitizer^{6,7}.

The compounds tested are conventionally grouped, as in Table 1. In general, *primary antioxidants* are considered to function as free-radical acceptors; *secondary antioxidants* act synergistically with primary antioxidants; and *ultra-violet absorbers* block the catalytic effect of ultra-violet and visible light. The *miscellaneous group*, comprised largely of reducing agents with free —SH groups, includes classical radioprotective agents not generally regarded as antioxidants.

From stock solutions of compounds in acetone or water at 0.1 or 0.01 g/ml., serial log dilutions of aqueous suspensions were freshly prepared from 3,000 to 0.3 μ g/ml. The dilution range was appropriately extended, occasionally to as low as 3×10^{-10} μ g/ml., for compounds with high activity. Aqueous suspensions of benzo(a)pyrene (BaP) at 0.1 μ g/ml., freshly prepared from stock acetone solutions of 100 μ g/ml., were used as the standard photosensitizing agent. Cultures of *Tetrahymena pyriformis* var 1, mating type II, were maintained axenically in the dark at 28° C in medium containing 1.5 per cent w/v 'Proteose®' peptone and 0.15 per cent w/v yeast extract at pH 6.8. Suspensions from log-phase cultures, diluted in medium to contain approximately 30 cells, were mixed on single 15 \times 4 mm plastic depression slides with aliquots of BaP and of individual concentrations of antioxidants. These slides, together with a minimum of two antioxidant-free controls, were incubated at 28° C in dark moist chambers for a minimum of 2 h. Two wells were then irradiated simul-

taneously with long-wave ultra-violet light, of 8.750 μ W/cm² at 45 cm, filtered to transmit light from 310 to 400 m μ with a peak at 366 m μ , and observed directly with a binocular stereoscopic microscope at a magnification of $\times 10$. The duration of irradiation required to produce lethality, as indicated by immobilization of 90 per cent of the motile ciliates (LT_{90}), was determined, with an arbitrary observation limit of 60 min. All compounds were tested a minimum of three times, using new stock solutions on at least two occasions.

Protection from photodynamic toxicity was manifest by prolongation of median LT_{90} over median control values (Table 2). Concentrations of compounds producing two-fold prolongation of LT_{90} values and dose-response slopes of these compounds were determined (Table 1 and Fig. 1). Approximately half the compounds tested (58/98) achieved such protection. α -Tocopherol was selected as the standard for apparent relative potency determinations (Table 1). For compounds yielding two-fold or greater protection, the possible role of light absorption was

Fig. 1. Method for determining the concentration of α -tocopherol required to produce two-fold prolongation of control LT_{90} values. α -Tocopherol was used as the standard for relative potency determinations. At 3,000 μ g/ml., LT_{90} values exceeding the arbitrary observational limit of 60 min are indicated by the arrow.

We acknowledge generous gifts of samples from the following sources: ¹, ³, ⁴, ⁷, ⁸, ⁹, ¹¹, ¹², ¹³.

† LT_{50} is the time in minutes required to immobilize 90 per cent of *T. pyriiformis*. Where a doubling of the LT_{50} was not achieved at the highest concentration tested, this is indicated by the > sign. In such instances, assay slopes and absorption values could not be determined.

‡ The prolongation of LT_{50} values resulting from interposing solutions of the compounds in a cuvette between the light source and mixtures of cells and BaP is expressed as a percentage of the prolongation of LT_{50} values as determined when the same concentration of compound is tested directly with cells and BaP, in the absence of the cuvette, as in the regular assays.

investigated by interposing a cuvette, containing an acetone or water solution of the compound in a 1-mm light path, between the irradiation source and wells containing cells and BaP only; compounds were generally tested at the minimum concentration producing maximum protection in antioxidant assays. The resulting LT_{50} values were compared with those of controls obtained with acetone or water in the cuvette.

The reproducibility of the assay is good (Table 2), although variation occurs on ageing of stock solutions, particularly with 'Butter Yellow' and 'Antabuse'. Protective activity increases progressively with concentration

of antioxidant (Fig. 1). The assay reveals wide variations in potency, spanning a 10 log range, although this is sometimes limited by cytotoxicity at high concentrations. Dose-response slopes tend to be shallow, and also parallel in the case of close structural variants such as hindered phenols of the triazine series, 'Ionox' compounds, or tocopherols (Table 1).

Comparable potencies obtain for the four tocopherol isomers and acetate or succinate esters of the α -isomer; *in vivo* hydrolysis of the esters to the presumed active free tocopherol is possible. The importance of solubility is suggested by the enhanced activity of the water-soluble glycol-succinate ester, although on a weight basis it contains only about 25 per cent α -tocopherol. Although the dimeric form of tocopherol has relatively feeble vitamin E activity on gestation-resorption bioassay⁸, it protects against photodynamic injury in a similar manner to the monomers. Antioxidants with reported vitamin E biopotency, such as methylene blue, EMQ, DPPD, NDGA, and 'Antabuse', are all active in the photodynamic bioassay; the latter two compounds in particular showing high activity. Phenols and the simple hindered phenols, BHA, BHT, and 'Ionox 100', are generally inactive in contrast to more complex phenols, such as the other

Table 2. PROTECTION OF *T. pyriiformis* FROM PHOTODYNAMIC TOXICITY OF BENZO(a)PYRENE BY VARYING CONCENTRATIONS OF α -TOCOPHEROL

Individual experiments	Time to 90 per cent lethality (min), with 0.1 µg benzo(a)pyrene, as photosensitizer, at specified concentrations, µg/ml., of α -tocopherol					
	3,000	300	30	3.0	0.3	0*
1	> 60	18	12	6.5	5.5	5.5
2	> 60	21	15	8	7.5	6
3	> 60	20	11	7.5	7.5	7
4	> 60	25	17	10	8.5	7

Medians	> 60	20	12	8	7.5	6.5

* Antioxidant-free control times represent means of 2-4 determinations in individual experiments.

'Ionox' antioxidants and the substituted triazines. The antioxidant activity of the aminoazobenzenes, previously described in other systems⁸, was generally found to be extremely high (Table 1), and 'Butter Yellow', for example, is almost one million times more potent than α -tocopherol. As it is unlikely that differences of such magnitude are explicable in terms of free radical acceptance alone, biological factors such as cell uptake, and selective localization or complexing, are probably involved. There is no apparent correlation between the hepatocarcinogenic and antioxidant activities of the aminoazobenzenes. (Hepatocarcinogenic potencies of aminoazobenzenes in rats: + + + +, Nos. 64, 66, 68; + + +, Nos. 56, 58, 60; + +, No. 62; +, Nos. 63, 65, 67; 0, Nos. 55, 57, 59, 61. No. 54 is hepatocarcinogenic in the mouse¹⁰.) Secondary antioxidants, palmitic and dilauryl esters of ascorbic, and 3,3'-thiodipropionic acids, respectively, showed activity in contrast to the acids. Since commercial samples of lecithin may be contaminated with tocopherol, the activities of lecithin and 'Viobin' observed here may reflect antioxidant synergism between lecithin and varying amounts of tocopherol. Apart from the very low potency of cysteamine, radioprotective agents were inactive. The cuvette experiments (Table 1) indicate the role of absorption in the demonstrated activity of primary antioxidants, such as 'Quercetin' and EMQ. Protection by some industrial ultra-violet absorbers, such as 'Tinuvin P', may be due to low transmittance at the 360 m μ region; however, the effects of others are not explicable in this way.

The present assay provides a sensitive biological measure of particular *in vivo* effects of certain antioxidants, but its general applicability and specificity cannot, as yet, be defined. Present experiments¹¹ indicate that, in general, antioxidants yield similar responses in

the photodynamic bioassay irrespective of which particular photosensitizing agent, carcinogenic or otherwise^{12,13}, is used and also that antioxidant activity is inversely related to the concentration of the challenge photosensitizer. Attempts are being made to define the quantitative interaction between antioxidant and photosensitizer, *inter alia*, by determination of inhibition indices, and also the role of cell-uptake in determining activity¹¹. The results of these *in vivo* assays are further being contrasted with those obtained by *in vitro* photodynamic bioassays, using isolated rat liver mitochondria¹¹, and by previously described *in vitro* haemolysis tests¹⁴. In addition, the effects of selected antioxidants on the response of mice to a polycyclic carcinogen are being investigated¹¹. These and other aspects of this work will shortly be reported.

This investigation was supported by Public Health Service research grant C-6516 from the National Cancer Institute.

THREE HAEMOGLOBINS K: WOOLWICH, AN ABNORMAL, CAMEROON AND IBADAN, TWO UNUSUAL VARIANTS OF HUMAN HAEMOGLOBIN A

By DR. N. ALLAN

Subdepartment of Haematology, University College Hospital, Ibadan, Nigeria

AND

D. BEALE, D. IRVINE and DR. H. LEHMANN

Medical Research Council Abnormal Haemoglobin Research Unit, University Department of Biochemistry, Cambridge

HAEMOGLOBIN K was first described by Cabannes and Buhr¹ and is a 'fast' variant of normal adult haemoglobin (haemoglobin A). It moves further towards the anode on electrophoresis at alkaline pH than haemoglobin A, but only just separates from it.

A haemoglobin K with its abnormality in the β -chain has been reported to occur in combination with haemoglobin S (ref. 2). The proportion of S : K was 3 : 2, and there was a mild haemoglobinopathy. The family in which this haemoglobin K was observed came from the West Indies and was of African ancestry. This haemoglobin K was first noted at Woolwich, England, and it will be denoted as K β Woolwich.

We have now found a second instance of the combination of a haemoglobin K with haemoglobin S. By hybridization with canine haemoglobin³ this haemoglobin K could be shown to be a β -chain variant. Unlike haemoglobin K Woolwich, the proportion of this haemoglobin K to haemoglobin S was 3 : 1, similar to that of haemoglobin A in the sickle-cell trait (A + S). There was no haemoglobinopathy. Indeed, the carrier of this K + S combination was found in the course of routine screening of healthy blood donors at University College Hospital, Ibadan, Nigeria. The blood donor, a woman, came from Cameroon, and neither she herself nor her relatives could be examined

further. This new haemoglobin K will be denoted as haemoglobin K β Cameroon (Figs. 1 and 2).

A third sample of haemoglobin K, this time in combination with haemoglobin A, was found in a Yoruba adolescent in Ibadan, in the course of an anthropological survey.

Fig. 1. Paper electrophoresis at pH 8.6 of haemoglobins K Cameroon + S (left) and S + K Woolwich (right). The proportion of K Cameroon to S is that found for A in sickle-cell trait (see Fig. 2).

Hybridization with canine haemoglobin showed the variant to have its amino-acid substitution in the β -chain. The proportion of A : K was 1 : 1, and there was no anaemia. The body was repeatedly examined; but in the members of the family available for examination no further instances of haemoglobin K were found. This haemoglobin K will be denoted as haemoglobin K β Ibadan.

It has previously been discussed that some haemoglobin variants may be recognized as 'abnormal' when in combination with haemoglobin A they are found to form less than half the total haemoglobin⁴. Others may be considered as merely unusual, and they can be recognized by being found in equal proportion to haemoglobin A. The combination A + S (A > S) is an example of the first, abnormal type, and that for A + G Accra (A = G) represents the second unusual type. On two occasions a combination of unusual haemoglobins with haemoglobin S was observed. Haemoglobin S was present as the lesser fraction, as it is found in sickle-cell trait carriers with haemoglobin A (A > S). Haemoglobin J Baltimore⁵ and haemoglobin D Ibadan⁶ were the two unusual haemoglobins which in combination with S formed the greater part of the total pigment. In both instances the carriers of the haemoglobin mixtures had no sickle-cell disease but were sickle-cell trait carriers.

Of our three haemoglobins K, the Woolwich variant can be described as abnormal, and the combination haemoglobin K Woolwich and haemoglobin S (K < S) causes a mild haemoglobinopathy. Haemoglobin K Cameroon together with haemoglobin S results in the sickle-cell trait (K > S), and haemoglobins K Ibadan and A are found in equal proportions (K = A). The two latter haemoglobins K are therefore unusual rather than abnormal. It was of interest to investigate these three haemoglobins which are similar in their electrophoretic properties, and if possible to see which amino-acid substitution in the β -chain changed the physiological value of the resulting variant, and which did not. The haemoglobins were isolated, peptide maps were prepared, and when possible the variant peptides were separated and analysed using the methods recently listed in detail⁶.

Haemoglobin K Woolwich. The peptide map of haemoglobin K Woolwich is shown in Fig. 3. It will be noted that the tyrosine peptide representing β A₁TpXIII and the

Fig. 3. Peptide map of haemoglobin K Woolwich. Note that at 1 β A₁TpXIII (positive for tyrosine), and at 2 β A₁TpXIV (positive for histidine) are missing. The incidental chymotryptic peptide β 131-132 derived from β A₁TpXIII is also missing at 3 (lower arrow) just below β A₁TpVI 3 (top arrow). A new peptide which was found to represent β A₁TpXIII-XIV can be seen at 4. The starred peptide is β A₁TpV in its usual position—compare with Fig. 6

histidine peptide β A₁TpXIV are missing, as well as a small spot near to β A₁TpVI that is usually present in peptide maps of haemoglobin A. An extended electrophoretogram (Fig. 5) showed these differences more clearly. β TpXIII represents residues 121-132 of the β -chain and β TpXIV residues 133-144.

A mutation affecting the mobility of both these tryptic peptides is likely to involve the lysine residue at position 132 because a change in the nature of this residue, apart from Lys \rightarrow Arg, would result in a peptide bond at β 132 which could not be broken by tryptic hydrolysis. In this case β TpXIII and β TpXIV would form one new peptide containing both tyrosine and histidine. Such a new peptide can be seen in Fig. 3, and it will be noted that it has moved somewhat towards the cathode, thus indicating a slight positive charge. This would eliminate the possibility of a Lys \rightarrow Glu mutation which would have given rise to a negatively charged peptide. This mutation was already unlikely on the basis of the electrophoretic mobility of haemoglobin K Woolwich. The mutation Lys \rightarrow Glu results in the acquisition of two negative charges per half molecule of haemoglobin and this would produce a variant with an electrophoretic mobility resembling that of haemoglobin I or haemoglobin N rather than that of haemoglobin K. The mutation Lys \rightarrow Arg has already been excluded. It would not give rise to a charge change and would not resist the tryptic separation of the β XIII and β XIV peptides. The remaining single mutations permitted by the genetic code⁷ are Lys \rightarrow Gln, Lys \rightarrow Asn, Lys \rightarrow Thr and Lys \rightarrow Met. The amino-acid analysis of the new peptide is given in Table 1. It will be seen that all the residues of β TpXIII and β TpXIV are present except for one lysine residue, and that one additional residue of glutamic acid was found. Glutamine is hydrolysed to glutamic acid when peptides are hydrolysed into their amino-acid constituents and the additional glutamic acid had to come from a glutamine, as the observed electrophoretic mobility of the new peptide demands. The lysine residue in position β 132 of the β -chain had thus been substituted by one of glutamine. Haemoglobin K Woolwich may be described as $\alpha_2\beta_2^{132}\text{Lys}\rightarrow\text{Gln}$. This represents the first observation of a Lys \rightarrow Gln mutation in human haemoglobin. The mutation also explains the absence of the small spot

Fig. 2. Paper electrophoresis at pH 8.9 of haemoglobins from sickle-cell trait (A + S) and of haemoglobins S + K Woolwich. The combination of haemoglobin S and K Woolwich shows a greater proportion of S and results in a mild haemoglobinopathy.

Lys	1	1	2	1.0
His		1		0.9

Low recovery of valine is probably due to slight resistance of Val-Val bond to acid hydrolysis.

usually found near βTpVI . This spot represents a dipeptide $\beta 131-132$ (Gln-Lys) resulting from an incidental chymotryptic splitting of the $\beta 130$ tyrosyl peptide bond during tryptic hydrolysis. No such dipeptide could, of course, arise when $\beta 132$ is Gln instead of Lys because the residues $\beta 131-132$ would remain attached to βTpXIV .

Haemoglobin K Cameroon. Unfortunately there was insufficient material available to make a complete structural investigation, and in spite of all efforts the donor could not be contacted again. The peptide map of this haemoglobin is shown in Fig. 4. It will be seen that the small spot usually found near βTpVI is missing and it is known that this spot represents the dipeptide $\beta 131-132$ (Gln-Lys) arising from an incidental chymotryptic splitting of βTpXIII during tryptic digestion. A very small shift of βTpXIII towards the anode is also noticeable. This alteration in the electrophoretic mobility of βTpXIII was confirmed by an extended electrophoretogram (Fig. 5). The increase in negative charge of βTpXIII is compatible with a haemoglobin K which differs from haemoglobin A by an additional negative charge per half-molecule. This, in βTpXIII , could only be the substitution of a neutral amino-acid residue by Glu or Asp. The absence of the incidental chymotryptic peptide from βTpXIII suggests that there was an inhibition of the chymotryptic splitting of the $\beta 130$ tyrosyl bond. Such an inhibition could be caused by a substitution of the neutral $\beta 129$ Ala residue by an acidic residue. Thus it seems likely that in haemoglobin K Cameroon a Glu or an Asp has replaced the Ala at $\beta 130$. Clearly these observations need substantiating when the opportunity arises.

Haemoglobin K Ibadan. The peptide map of haemoglobin K Ibadan is shown in Fig. 6. It will be seen that

the methionine peptide βATpV is missing, and a new methionine peptide has appeared moving further towards the anode with an electrophoretic mobility similar to that of βTpIII . This alteration in electrophoretic mobility of βTpV could be confirmed in an extended electrophoretogram (Fig. 7). βTpV represents residues 41-59 of the β -chain.

Thr	1.0	1.0
Ser	2.0	1.8
Glu	1.0	2.0
Pro	2.0	1.9
Gly	1.8	1.0
Ala	1.2	1.0
Val	1.1	0.8
Met	0.8	Present*
Leu	1.1	1.1
Phe	2.4	2.5
Lys	1.2	1.1

* Methionine and sulphone together amounted to about 1 residue.

The amino-acid analysis of the new peptide, from haemoglobin A, is shown in Table 2. It will be seen that the new peptide contains one glycine residue less and one glutamic acid residue more than the haemoglobin A peptide. A mutation Gly \rightarrow Glu would explain the increase in the negative charge of βKTpV and would be compatible with the new variant being a haemoglobin K which has one negative charge per half-molecule more than haemoglobin A. Consistently low recoveries were obtained for phenylalanine. This can be seen also in a previous analysis of βTpV . The Phe-Phe bond may be difficult to hydrolyse because of steric effects. Increasing the time of hydrolysis from 20 h to 40 h at 108° did not improve recovery.

βATpV contains two glycine residues: $\beta 46$ and $\beta 56$. In order to determine which of the two possible glycine residues had been replaced by glutamyl, the methionyl bond at $\beta 55$ was split with cyanogen bromide. The resulting peptides were separated by paper electrophoresis at pH 6.4. βATpV isolated from haemoglobin A was treated similarly. From both βKTpV and βATpV two fragments each were obtained, one charged positively, and one charged negatively. The positively charged peptides obtained from βKTpV and βATpV had the same electrophoretic mobility, whereas of the two negatively charged peptides, that from haemoglobin K had a greater mobility. If the amino-acid substitution Gly \rightarrow Glu in haemoglobin K Ibadan had been at $\beta 56$ no positively charged peptide

Fig. 4. Peptide map of haemoglobin K Cameroon. Note that a 1 $\beta\text{ATpXIII}$ (positive for tyrosine) is missing. The chymotryptic dipeptide $\beta 131-132$ derived from $\beta\text{ATpXIII}$ is also missing at 2 (lower arrow), just below βATpVI 2 (top arrow). 3 indicates the new peptide $\beta\text{KTpXIII}$. The starred peptide is βATpV in its usual position—compare with Fig. 6.

would have resulted from the cleavage of the methionyl bond at $\beta 55$. Both the positively charged peptides from A and K, presumably representing residues $\beta 56-59$, stained transiently yellow with ninhydrin, indicating the *N*-terminal glycyl. The increased mobility of the negatively charged peptide from haemoglobin K Ibadan indicated that the mutation had occurred at position $\beta 46$. The results of the amino-acid analysis of the four fragments are shown in Table 3. The basic amino-acids were not determined as this was not relevant to the position of the Gly \rightarrow Glu mutation. It will be seen that the positively charged peptides (56-59) from $\beta KTpV$ and $\beta ATpV$ have an identical amino-acid composition. However, the negatively charged peptide representing residues 41-55 from $\beta KTpV$ has one glutamic acid residue more and one glycine residue less than the corresponding negatively charged peptide from $\beta ATpV$. This indicates that of the two glycine residues 46 and 56 the first has been substituted by glutamyl and that the formula of haemoglobin K Ibadan is $\alpha_2\beta_2^{46} \text{Glu} \rightarrow \text{Glu}$. This is the first observation of a Gly \rightarrow Glu mutation in human haemoglobin although a mutation Glu \rightarrow Gly has been observed¹⁰.

Table 3. HAEMOGLOBIN A AND HAEMOGLOBIN K IBADAN
Amino-acid analysis (molar ratio) of peptides arising from splitting βTpV ($\beta 41-59$) at $\beta 55$ methionyl with cyanogen bromide

Electrophoretic mobility at pH 6.4 (Glu, -1.0, Lys, +1.0)	Negatively charged peptides ($\beta 41-55$)		Positively charged peptides ($\beta 56-59$)	
	Hb A	Hb K	Hb A	Hb K
Asp	2.0	2.2	1.0	1.0
Thr	1.0	1.0		
Ser	2.0	1.8		
Homoserine	Present	Present		
Glu	1.2	1.9		
Pro	1.0	1.1	1.0	0.9
Gly	1.0	0.3	0.9	1.0
Ala	1.1	1.0		
Val	1.1	1.0		
Leu	1.0	1.0		
Phe	2.4	2.3		

It has been suggested here that haemoglobin K Cameroon (mutation of $\beta 130$ Ala to Asp or Glu?) and haemoglobin K Ibadan ($\alpha_2\beta_2^{46} \text{Glu}$) are unusual haemoglobins whereas haemoglobin K Woolwich ($\alpha_2\beta_2^{132} \text{Gln}$) is abnormal. It is remarkable that the $\beta 132$ lysine residue, which is substituted by one of glutamine in haemoglobin K Woolwich, is one of the most immutable residues in the evolution of haemoglobin. It is also found in myoglobin, and indeed no haemoglobin has as yet been described in which this $\beta 132$ lysyl is not present. The lysyl in this

Fig. 6. Peptide map of haemoglobin K Ibadan. $\beta ATpV$ is missing at 1, and a new peptide can be seen at 2, with the electrophoretic mobility of $\beta ATpIII$ (3). The starred peptide is the incidental chymotryptic dipeptide $\beta 31-132$ from $\beta ATpXIII$ which is missing in Figs 3 and 4

Fig. 7. Paper electrophoresis (90 min at pH 6.4) of methionine containing peptides from haemoglobin A and haemoglobin K Ibadan. Note the increase in mobility of the negatively charged βTpv from haemoglobin K Ibadan

position must obviously serve some purpose in stabilizing the molecule and its replacement by an amino-acid with a neutral side-chain may thus be expected to interfere with the *status quo* within the molecule.

APOFERRITIN SYNTHESIS IN HUMAN ERYTHROID CELLS IN THALASSAEMIA

By DR. EDWIN H. EYLAR* and DR. GASTONE MATIOLI

Departments of Biochemistry and Microbiology, University of Southern California School of Medicine, Los Angeles

A LARGE amount of iron in the form of ferritin and haemosiderin has been revealed in thalassaemic erythropoietic cells by histochemical and electron-optical techniques^{1,2}. One hypothesis claims that ferritin is transferred to the erythroblasts from the macrophages where it is actively synthesized. Recent investigations^{3,4} on rabbit reticulocytes, however, point out that ferritin biosynthesis occurs in erythroid cells. This article describes the biosynthesis of apoferritin by normal and thalassaemic

erythropoietic cells isolated from human bone marrow as well as by reticulocytes. It was found that apoferritin biosynthesis is greatly enhanced in thalassaemia.

Reticulocytes from peripheral blood and erythroblasts isolated from bone marrow were obtained from patients affected by thalassaemia and acute bleeding anaemia. Bone marrow (15-20 ml.) was removed by puncture of the two iliac crests and superior iliac spines. All the procedures described here were carried out at 4°. In order to dissociate cells from the bone marrow fragments, the

*Markle Scholar in academic medicine.

material was gently forced three or four times through the free space of a loosely fitted silicone-coated syringe. The cell suspension was washed three times in cold saline and passed through twenty layers of cheese cloth. The suspension of cells was then centrifuged, and the cells were resuspended in 3 volumes of a 2 per cent solution of fetuin prepared from foetal calf plasma by column chromatography on DEAE-'Sephadex'. The cell suspension in fetuin was applied to a column (2 cm \times 15 cm) containing tightly packed glass wool and the cells eluted slowly by addition of 1 per cent fetuin solution. After again passing the cell suspension through a similar column, the population of cells was represented by red blood cells, reticulocytes and erythroblasts at different stages of maturation, lymphocytes and eosinophils. The other cells (granulocytes, macrophages, megakaryocytes, etc.) were not detected in stain preparations or in phase contrast microscopy. These cells probably remained attached to the glass wool or were destroyed. The eluted cells were washed several times in saline, packed by centrifugation and applied in volumes not exceeding 0.4 ml. per tube to a linear albumin density gradient⁵ ranging between 1.100 and 1.065 and spun at 13,000 r.p.m. in a Spinco model L ultracentrifuge SW 39 rotor at 4°. After spinning for 1 h, the cells were distributed in six rather sharply defined bands. The third, fourth and fifth bands from the top were represented by a mixture of red blood cells (70–75 per cent), reticulocytes (10–20 per cent), and erythroblasts (5–10 per cent) at various stages of maturation, particularly polychromatophylic and orthochromatic erythroblasts. Less than 0.5 per cent eosinophils or lymphocytes were seen. The bands containing the erythroid cells were removed by slicing the tube or by aspiration, and the cells were washed three or four times in cold saline to remove the albumin. The cells were consequently incubated in the media previously described⁴.

Large amounts of peripheral blood (150 ml.) in heparin were collected in siliconized tubes. In order to enrich the reticulocyte population, the blood was centrifuged at 4° at 250*g* for 20 min, and the top layer of cells was removed. The percentage of reticulocytes in different blood samples was increased roughly two-fold by this enrichment process. The buffy coat was removed as completely as possible and the cells were washed in cold saline four times, then incubated as previously reported⁴.

For incubation at 37°, the modified Krebs-Ringer solution was used. For reticulocytes from peripheral blood, the ratio of packed cell volume to incubation media was about 0.4. In every 7 ml. of incubation media, 10 μ c. of ¹⁴C-L-leucine (Volk Chemical Co.) with specific activity of 180 mc./mmole was added. The cell population contained 7–11 per cent reticulocytes and no white cells. The volume of reticulocytes was evaluated by multiplying the haematocrit by the per cent reticulocytes.

For the erythroblast preparations, approximately 6 ml. media was used for every 1 ml. packed cells which contained about 5–10 per cent erythroid cells with the reticulocyte: erythroblast ratio varying from 1:1 to 2:1 to 1:2 for different preparations. About 7.5 μ c. of ¹⁴C-L-leucine was added per 6 ml. incubation media. Under these conditions no perceptible haemolysis occurred even up to 3 h. The volume of erythroblasts was computed by multiplying the haematocrit by the volume per cent of erythroblasts assuming spherical cells and a volume ratio of 2.3:1 for erythroblasts to erythrocytes⁶.

After haemolysis of the reticulocyte or erythroblast preparations, the solution was centrifuged at 20,000*g* for 20 min to remove stroma and mitochondria under conditions described previously⁴. Very little haemoglobin was left in the precipitate after washing once with 0.15 M sodium chloride at pH 8.5. The ferritin was isolated from the combined supernatant and wash solutions by adding an excess of antiserum⁴ obtained from rabbits. Immunization of the rabbits⁴ was carried out with human ferritin prepared from liver which had been obtained from cases

of severe haemachromatosis. It was crystallized three times with 20 per cent cadmium sulphate and contained no traces of contaminating proteins as revealed by starch-gel electrophoresis at pH 8.6, ionic strength 0.02.

The incorporation of ¹⁴C-leucine into ferritin of reticulocytes from peripheral blood is shown in Fig. 1. The biosynthesis of ferritin was found in all the patients, and from Fig. 1 it is clear that ferritin synthesis in thalassaemia (curves A and B) is greatly increased over the controls. Our technique measures only the activity of the soluble ferritin and apoferritin of the 15,000*g* supernatant fluid, and thus the activity associated with haemosiderin or ferritin of the mitochondria, nuclei, or stroma would be missed. The apoferritin synthesis shown in curve A (Fig. 1) is about 37-fold increased over the controls (curves C and D) after 30 min. Much variation was found in the abilities of the reticulocytes from different patients with thalassaemia to synthesize ferritin as shown by curves A and B. The maximal synthesis was found with a 24-month-old girl with very severe clinical symptoms. The variation in general in reticulocytes seemed to correlate roughly with the severity of the anaemia as judged clinically. None of the patients of this investigation had been transfused within one year or longer, and all thalassaemic patients had 75–95 per cent haemoglobin F.

Fig. 1. Incorporation of ¹⁴C-L-leucine found in isolated ferritin, measured as c.p.m./ml. packed reticulocytes, is plotted as a function of time of incubation. Curves A and B represent cases of thalassaemia and curves C and D represent cases of acute bleeding anaemia. The incubation conditions at 37° and isolation of the ferritin are described in the text.

The incorporation of ¹⁴C-leucine into ferritin of erythroblasts isolated from bone marrow is shown in Fig. 2. Again, as with the reticulocytes, the ferritin synthesis in thalassaemia is greatly elevated over the control. Here, also, there is much variation between patients. This variation, however, unlike the situation with the reticulocytes, could not be correlated directly with the severity of the clinical symptoms. For example, curve A represents a case of mild thalassaemia (judged clinically) while curve C, which is only slightly above the normal, represents very severe anaemia.

The incorporation of ¹⁴C-leucine into apoferritin in human reticulocytes and erythroblasts in thalassaemic and non-thalassaemic cases agrees with earlier results⁴ which showed that rabbit reticulocytes were able to synthesize apoferritin. These results offer direct proof for the intracellular origin of ferritin, and initiate new questions concerning the interrelationships of iron-containing macromolecules within the cell. In thalassaemia the ferritin synthesis is greatly elevated as seen from Figs. 1 and 2 in both reticulocytes and erythroblasts. A comparison of the ratio of ferritin to haemoglobin synthesis shown in Table 1 illustrates more validly and dramatically the

Fig. 2. Incorporation of ^{14}C -L-leucine into the isolated ferritin, measured as c.p.m./ml. packed erythroblasts, is plotted against time of incubation at 37° as described in the text. Curve A represents a case of thalassaemia with mild clinical symptoms whereas curves B and C represent severe thalassaemia. Curve D was obtained with erythroblasts from a case of acute bleeding anaemia.

enhanced ferritin synthesis in thalassaemia. The possible objections to comparison of different cell populations because of variation due to factors like polysome concentration, rate of amino-acid transport, age of cell, and environmental differences are obviated. Furthermore, the biosynthetic abilities of reticulocytes and erythroblasts correlate with electron microscopic results which show greatly elevated levels of ferritin and haemosiderin in thalassaemia. A rough calculation can be made from the results shown in Fig. 1 (curve A) to show that thalassaemic reticulocytes synthesize ferritin at the rate of $0.7 \mu\text{g}$ per 48 h per cell. For erythroblasts, the *in vitro* synthesis of ferritin (curve A, Fig. 2) is calculated to be $3\text{--}6 \mu\text{g}$ of ferritin per 48 h per cell in thalassaemia. These figures compare favourably with the $2\text{--}3 \mu\text{g}$ of ferritin and haemosiderin estimated to be present in the thalassaemic erythroblasts⁷. The calculated rate of ferritin synthesis represents a minimal value since only soluble ferritin of the $15,000g$ supernatant fluid was measured. The specific activity of the leucine is probably reduced by residual leucine in the intracellular pool, and some messenger RNA (mRNA) is probably destroyed as the reticulocytes mature. It is apparent nevertheless that the erythroid cell is capable of synthesis of much of its ferritin and haemosiderin, if not all of it. There would be little reason, therefore, for macrophages to transfer ferritin to the erythroid cell as suggested by Bessis and Breton-Gorius². Rather the macrophage system may acquire it by transfer

from erythroblasts, reticulocytes and erythrocytes in the interest of iron conservation. Furthermore, the iron of the ferritin normally found in reticulocytes and erythroblasts in thalassaemia represents 5–7-fold greater iron⁷ than found in the haemoglobin of a normal cell. It appears, therefore, that ferritin in erythropoietic cells need not be used as an iron depot for haemoglobin synthesis⁸ and may function in other biological roles.

Most of the thalassaemic patients of this investigation had never been transfused; consequently, it cannot be claimed that the increased ferritin biosynthesis is due to iron overloading. Variations in both haemoglobin and ferritin biosynthesis occurred among different cases. With reticulocytes the variation in ferritin synthesis roughly paralleled the severity of the thalassaemia. With erythroblasts, the variation in ferritin synthesis could reflect, in addition to the other factors mentioned above, the age and type of the erythroblasts. It is certainly not likely, however, that the variation between cell populations from normals and thalassaemics could account for the greatly increased ferritin synthesis in thalassaemics since similar conclusions were derived from results with reticulocytes, which represent a more homogeneous population than erythroblasts. In order to eliminate the variation between cell populations from different patients, the ratio of synthesis of ferritin to haemoglobin for both reticulocytes and erythroblasts are tabulated in Table 1. Although average haemoglobin synthesis is reduced in the thalassaemic condition in our work—about 50 per cent in erythroblasts and 30 per cent in reticulocytes—the haemoglobin synthesis nevertheless serves as a valid frame of reference to judge the ferritin synthesis because the latter is so greatly elevated. Table 1 shows a 10–40-fold increase (1,000–4,000 per cent) in the ratio of ferritin to haemoglobin synthesis in thalassaemics with respect to the normals for erythroblasts and reticulocytes respectively. Correction for lowered haemoglobin synthesis gives a figure of 5–28-fold increase of ferritin synthesis of thalassaemic erythroblasts and reticulocytes over normals. Although the cells from the 2 thalassaemic cases in Table 1 showed widely different abilities to synthesize protein (curves A and B of Fig. 1), the ratios are in good agreement. Table 1 also illustrates that erythroblasts show a greater ferritin to haemoglobin ratio than reticulocytes in both the normal and thalassaemic state. These results would be anticipated on the basis of microspectrophotometric data⁹, which showed that ferritin synthesis precedes haemoglobin synthesis in the pronormoblast and basophilic erythroblast stages.

In β -thalassaemia, the average amount of haemoglobin per cell is reported to be about 15–25 per cent less than the normal⁹. It would appear logical that the enhanced production of ferritin in thalassaemia could account in large measure for this reduction. The early increase of synthesis of ferritin in young erythroblasts in thalassaemia could lead to a decrease in the cellular iron available for haemoglobin production⁴. There are no evidences that ferritin iron is utilized for haemoglobin synthesis⁸. Apoferritin molecules bind approximately 500 times as many iron atoms as haemoglobin, and its increase could reduce haemoglobin synthesis, which is known to be responsive to levels of iron concentration, by a negative feedback. Another alternative, of course, is that the ferritin biosynthesis is increased as a consequence of hypothesis of haemoglobin. Because iron induces both proteins, the existence of a block in the biosynthesis of haemoglobin would allow more iron to induce apoferritin synthesis and react with apoferritin to make ferritin. Against this possibility, however, stands the very high concentration of ferritin found both by cytochemical and biochemical methods, which cannot be accounted for by the difference between the iron used for production of haemoglobin in normal erythrocytes and thalassaemic cells. In fact, while normal erythrocytes use $0.1 \mu\text{g}$ of iron to make $30 \mu\text{g}$ of haemoglobin a large proportion

Table 1. A COMPARISON OF THE RATIOS OF RADIOACTIVITY IN ^{14}C -LEUCINE FOUND IN ISOLATED FERRITIN AND TOTAL HAEMOGLOBIN IN RETICULOCYTES AND ERYTHROBLASTS

	Ratio of c.p.m. in ferritin $\times 10^4$ to the c.p.m. in haemoglobin/ml. cells	
	Thalassaemia	Normal
Reticulocytes	120	2.5
	110	
Erythroblasts	230	21
	170	

The conditions of the incubation and the isolation of the ferritin are described in the text. The amount of radioactivity in the haemoglobin was determined as follows: the $20,000g$ supernatant fluid was adjusted to 50 per cent saturation with ammonium sulphate (pH 7.0). After setting 1 h at room temperature, the solution was centrifuged, and the precipitate was washed once with 50 per cent ammonium sulphate. The combined supernatant fluid and wash solution were combined with an equal volume of 10 per cent trichloroacetic acid. The precipitate was washed, and the radioactivity determined as described elsewhere (ref. 4).

of thalassaemic erythrocytes make 15 μg of haemoglobin, leaving then 0.05 μg of iron for ferritin⁷. The amount of iron bound to ferritin, however, is 5–7 times larger (that is, 0.250–0.350 μg or more). It is obvious that the total lack of information concerning the expression of the ferritin gene makes it very difficult to discuss the high production of ferritin within the genetic framework of present interpretations of thalassaemia. Ferritin is present in concentrations comparable to those found in thalassaemia in erythroblasts of patients with refractory anaemias with sideroblastic marrow. The fact that 30 per cent of these patients have haemoglobin F sometimes in high amounts (12 per cent) with no evidence for a hereditary basis¹⁰ may open the question of existence of causal relationship between anaemia, production of haemoglobin F and high synthesis of ferritin outside of a rigid hereditary sequence.

We thank Dr. Thomas Bothwell, University of Witwatersrand, Johannesburg, South Africa, for supplying

us with antiserum to human ferritin, and the staff of the Clinica Medica, Cagliari, Sardinia, for the use of laboratory facilities. We also thank Miss M. Washington and Miss T. Laico for assistance and Mr. Larry Gaeta of Hyland Laboratories for a gift of foetal calf serum.

FORMATION OF INTRA-MITOCHONDRIAL GLUCOSYL-OLIGOSACCHARIDES FROM GLUCOSE BY INTACT NOVIKOFF ASCITES HEPATOMA CELLS

By DR. V. N. NIGAM and DR. G. DE LAMIRANDE

Montreal Cancer Institute, Notre Dame Hospital, and University of Montreal, Canada

AN amylomaltase able to synthesize glucosyl-oligosaccharides from maltose has been found in both animal and plant tissues^{1–3}. The presence of endogenous glucosyl-oligosaccharides has been reported in rat liver⁴ and their formation from ¹⁴C-glucose observed in rat diaphragm⁵. Of particular interest are the results of Sie *et al.*⁶, who obtained higher specific activity in oligosaccharides as compared with glycogen soon after NaH¹⁴CO₃ was administered to starved rats treated with cortisol. They concluded that glucosyl-oligosaccharides may be involved in the mechanism of glycogen synthesis. Olavarria⁷, on the other hand, using a partially purified glycogen synthetase of rat liver, has been able to obtain oligosaccharides of higher specific activity than glycogen only at longer periods of incubation, and concludes that they are formed by the degradation of newly formed exterior chains of glycogen by a contaminating enzyme. However, the two experimental systems are different from each other and the results from the purified system do not imply that glycogen formation *in vivo* cannot proceed through the formation of smaller intermediates. The priming action of glucosyl-oligosaccharides, when present in higher concentrations, has been demonstrated for glycogen synthetase⁸.

Our interest in the mechanism of glycogen synthesis originated from the observed inability of tumours to store glycogen. Although initial investigation has revealed that in Novikoff ascites hepatoma phosphoglucomutase activity is greatly reduced (it is 3.0 μmole G1P conversion to G6P per min per ml. packed cells; rat liver has 43 similar units per g wet weight) and glycogen synthetase activity is also diminished (it is 0.88 μmole ¹⁴C-glucose incorporated from UDP-G-¹⁴C per min per ml. packed cells as compared with 2.8 similar units per g wet weight of rat liver), the tumour cell is nevertheless able to synthesize glycogen at rates higher than those observed for rat liver slice. Fig. 1 shows the time-course of glucose incorporation into glycogen by the washed intact Novikoff ascites hepatoma cells⁹, suspended in the incubation medium described by Wu and Racker¹⁰. It can be seen that the rate of glycogen synthesis approximates to 1.1 μmole per min per ml. packed cells (rat liver slice has 0.2–0.4

μmole per min per g wet tissue). Watanabe¹¹ working with AH-130 hepatoma cells, and Alpers *et al.*¹² with HeLa cells, have also reported significant glycogen-synthesizing capacities in these tumours. Thus, it appears that in spite of a severe decrease in enzymatic activity of certain key enzymes the glycogen synthesizing activity still persists in the tumour.

These facts, taken together with the work of Sie and Fishman, and of Beloff-Chain, suggest the possibility of an alternative pathway for glycogen synthesis. The results reported here tend to support the conclusion of Sie *et al.*⁶ that an oligosaccharide route to glycogen may exist.

Novikoff ascites tumours cells were prepared as described before⁹. They were suspended for 15 min in ice-

Fig. 1. Time-course of glucose incorporation into glycogen by intact Novikoff ascites hepatoma cells. The digest consisted of 0.9 ml. cell suspension (0.2 ml. packed cells) in *tris*-incubation medium and 0.1 ml. solution in *tris*-incubation medium of 10 μmoles glucose-1-¹⁴C (100,000 c.p.m.). The reaction was carried out in 20-ml. beakers kept in a Dubnoff shaker flushed with oxygen at 37°. Glycogen was isolated by the KOH method and counted.

cold 1/4-strength *tris*-wash medium of Wu and Racker¹⁰ free of phosphate buffer, to allow easy breakage of the tumour cells later¹³. They were centrifuged in the cold and the sedimented cells were mixed with 2.0 ml. ice-cold distilled water and transferred to a 100-ml. Erlenmeyer flask. The thick suspension was rapidly brought to room temperature and 75 μ moles of glucose-1-¹⁴C (1×10^6 c.p.m.) was added (0.5 ml.) and the mixture was shaken in the presence of oxygen for 60 sec. After this short incubation, the cells were chilled and five volumes of cold water added; the cells were homogenized as described by Hawtree and Silk¹³. To the homogenate enough 1 M sucrose was added to make the mixture 0.25 M with respect to sucrose concentration. The homogenate was subjected to differential centrifugation and the mitochondrial fraction was isolated¹⁴. It was washed twice with cold 0.25 M sucrose. The second wash showed only traces of radioactivity. The packed mitochondrial fraction was then suspended in ice-cold water and a fraction was placed on the planchet, dried and counted using a Picker X-ray counter. Table 1 shows the number of counts obtained in the mitochondrial fraction from cells treated with ¹⁴C-glucose in the absence and presence of 2,4-dinitrophenol. It can readily be seen that glucose incorporation into the mitochondrial fraction takes place only when oxidative phosphorylation is possible.

Table 1. RETENTION OF RADIOACTIVITY BY TUMOUR MITOCHONDRIA ISOLATED AFTER INCUBATION OF INTACT TUMOUR CELLS WITH GLUCOSE-1-¹⁴C, IN THE PRESENCE AND ABSENCE OF 0.25 mM DINITROPHENOL

The counts are corrected for internal absorption due to traces of sucrose. Experimental details are described in the text. Total c.p.m. in the mitochondrial fraction/ml. packed cells

Exp. No. Additions	1	2	3
None	4×10^3	7.5×10^3	7.2×10^3
DNP	450	750	780

The identity of the labelled product in the mitochondrial fraction was established as follows. The washed mitochondrial fraction was extracted with 50 per cent ethanol. It was centrifuged and the supernatant removed. The precipitate was washed once more with 50 per cent ethanol and the alcoholic solution was recombined with the first supernatant. The solution was evaporated to dryness *in vacuo*. The material obtained was extracted with methanol (5 ml.), centrifuged to remove the precipitate, and re-evaporated to dryness *in vacuo*. The sugars were dissolved in 0.4 ml. methanol. In various experiments, 20–40,000 c.p.m. were recovered as sugars associated with the mitochondrial fraction per 4–5 ml. packed cells. The methanolic solution of the sugars was subjected to chromatography on paper as described by Giri and Nigam¹⁵. The chromatogram was developed with aniline diphenylamine phosphate¹⁵ whereon the presence of glucosyl-oligosaccharides became apparent. Fig. 2 shows a facsimile of the chromatogram obtained, together with a reference mixture of glucose, sucrose, maltose, maltotriose and maltotetraose. The lower bands and maltose gave the typical blue colour indicative of 1–4 glucosidic linkages¹⁶. When the bands corresponding to oligosaccharides and glucose were eluted the percentage distribution of radioactivity was roughly of the following order: glucose, 35–45; maltose, 10–15; maltotriose, 20–25; maltotetraose, 20–25; maltopentaose, 10–15.

In control experiments when labelled glycogen (obtained after incubation of tumour cells with glucose-1-¹⁴C and isolated by the KOH method, 150,000 c.p.m.) was added to the tumour homogenate and the mitochondrial fraction isolated and washed as described here, no detectable counts remained with the mitochondrial fraction. Similarly, added labelled glucose was not adsorbed on the mitochondria even after 30 min incubation at room temperature.

Fig. 2. Sector of a circular-paper chromatogram showing the presence of glucose (band 1), maltose (band 3), maltotriose (band 4), maltotetraose (band 5) and maltopentaose (band 6) in the mitochondrial extract of Novikoff ascites hepatoma cells (U). Presence of sucrose (band 2) is due to the use of sucrose after homogenization. Band 2 has little radioactivity. M represents a synthetic mixture of glucose, sucrose, maltose, maltotriose and maltotetraose, numbered 1 to 5 in the order of decreasing R_f values. Developing solvent: acetone-butanol-water (7 : 2 : 1). Spraying reagent: aniline diphenylamine phosphate

The presence of oligosaccharides in the mitochondrial fraction raises two questions. Are they the degradation product of glycogen by amylase when both sediment with the mitochondrial fraction, or are they in the process of being built into glycogen? It appears improbable that these saccharides of low molecular weight will sediment with the mitochondria. Furthermore, all operations after the incubation are carried out at 0°–5°, and immediately after the mitochondrial fraction is obtained 50 per cent ethanol is added. Under these conditions amylase-mediated degradation of glycogen appears unlikely.

We interpret our results as indicative of an initial reaction of glucose at the mitochondrial level in the respiring intact cell which leads to the formation of a high-energy glucosyl precursor of oligosaccharides and glycogen. Such a compound may have the capacity to accept glucosyl residues from suitable donors to form short or long glucosidic chains, depending on the period and conditions of incubation. Since the amount of glycogen formed by intact cells subjected to hypotonic treatment is small and the formation of oligosaccharides relatively significant, it seems likely that the oligosaccharides are on the route to glycogen. They may have a high turn-over rate perceptible only when the rate of glycogen formation is reduced by hypotonicity. Whether they act solely as primers or their presence reveals a step-wise build-up of glycogen molecules has yet to be ascertained. Extremely low content of glycogen in the freshly prepared tumour cells may suggest that they also could act as primers. This investigation has been supported by a grant to Dr. A. Cantero from the National Cancer Institute of Canada. We thank Dr. W. H. Fishman for assistance.

GUANASE ACTIVITY OF THE SYMBIONTS AND FAT BODIES OF THE COCKROACH, *Leucophaea maderae*

By DR LEON L. PIERRE

Department of Biology, Long Island University, Brooklyn I, New York

GUANASE is an enzyme which is commonly found in the tissues of animals, as evidenced by the conversion of guanine (a degradation product of nucleic acids) to xanthine. Anderson¹ found the enzyme in high concentration in the fat bodies of the cockroach, *Periplaneta americana*, the armyworm, *Prodenia eridania*, and the mealworm, *Tenebrio molitor*. Similarly, Lisa and Ludwig² found it in the fat body of the normal cockroach, *Leucophaea maderae*. The purpose of this investigation is to determine whether this enzyme is produced by the symbionts, the fat body, or both in the cockroach, *L. maderae*.

The symbionts and fat bodies used in these experiments were cultivated or prepared according to the method of Pierre³. Recent modification of this method facilitates an easier isolation of the symbionts by exposure of the bared abdominal cavity once to the 70 per cent ethanol for 5–10 min, and then substitution of the sterilizing solution for ethanol in each case afterwards. 500 mg material obtained from the symbionts (cultures 24–48 h old) and aposymbiotic adult and nymphal fat bodies (sixth to eighth instar nymphs) were used in the isolation of guanase. The material was homogenized with a motor-driven homogenizer in 8 ml. of distilled water, and allowed to stand for 25 min to permit further extraction. It was then subjected to high-speed centrifugation at 15,000 r.p.m. *in vacuo* at 0° C for 25 min, and further extraction was performed according to the method of Kalckar⁴ as modified by Lisa⁵.

The substrates guanine and xanthine were prepared by dissolving 1 mg of each singly or together in 1 ml. of 0.01 N NaOH. 1 ml. of each substrate or the mixture of both substrates and 1 ml. of the particular enzyme fraction were placed in the main portion of a Thunberg tube, evacuated for 5 min, and then immersed in a constant temperature water-bath at 38° C for 2 h. This temperature is most favourable for the activity of guanase while it inhibits traces of xanthine which invariably accompany the isolation of guanase. At the end of incubation, the proteins in the mixtures were destroyed with 10 per cent perchloric acid, and the deproteinized mixtures were centrifuged at 2,000 r.p.m. for 5 min. 0.5 ml. of the supernate were added to 9.5 ml. of 0.1 N NaOH, and 3 ml. of the mixture were assayed against 3 ml. of 0.1 N NaOH in the Beckman DU spectrophotometer according to the method of Block and Johnson⁶. Verification of the results obtained by this method was evidenced by an assay of incubated mixtures after 1 and 2 h periods according to the method of Roush and Norris⁷. Final confirmation of both methods of assay was obtained by subjecting the deproteinized mixtures to ascending chromatographic studies. Strips of Whatman No. 1 chromatographic paper (6 × 35 cm) were spotted at one end with one lambda portion of the mixtures. One end of the paper was immersed in the solvent (50 ml. butanol + 15 ml. ethanol + 35 ml. distilled water), and the other hung loosely in a cylindrical jar. The top of this jar was sealed and the papers were left for a day. At the end of 24 h, the papers were taken out and air-dried. Spots appearing on the papers were discovered by means of an ultra-violet lamp. These spots were circled with a lead pencil, cut out and eluted in 10 ml. of 0.1 N NaOH. The eluted mixtures were read spectrophotometrically at 260 and 280 mμ. The *R_F* values of the substrates were obtained from the position of the spots on the chromatographic paper. At least five determinations of the activity of substrate and enzyme were performed at a time.

The results of this investigation, performed by the methods of Block and Johnson⁶, and Roush and Norris⁷,

and by chromatographic procedure, revealed that guanine was completely converted to xanthine by each fraction of the enzyme guanase. A noticeable shifting of the minimum and maximum absorption peaks of guanine (240 and 270 mμ) to those of xanthine (260 and 275 or 280 mμ) occurred when this substrate was incubated with the enzyme at 38° C for 2 h according to the method of Block and Johnson⁶ (Fig. 1). A similar activity of the enzyme on the substrate was observed when assays were made according to the method of Roush and Norris⁷ (Fig. 2), and by chromatographic studies (Fig. 3). No change in the absorption peaks of xanthine occurred when this substrate was incubated with the enzyme. Similarly, no change in the absorption peaks of guanine occurred when this substrate was incubated without the enzyme fractions. Mixtures of xanthine and guanine incubated with the enzyme and then assayed also showed evidence of the conversion of guanine to xanthine.

Assays made according to the method of Block and Johnson⁶ revealed that the enzyme fractions from the symbionts, adults and nymphs lowered the optical density of the substrate to the extent of -0.150, -0.148, -0.94 respectively. Corresponding values for this lowering of the optical density when assays were made after the 1-h period of incubation according to the method of Roush and Norris⁷ were -0.140, -0.150 and -0.53 respectively. Similarly, the respective values obtained for the decrease in density when guanine and xanthine were incubated together with the enzyme were -0.110, -0.110 and -0.98. The overall extent in the decrease in density over a 2-h period was 33.3 per cent.

The results of these experiments reveal a high activity of the enzyme guanase in the symbionts and fat body of the cockroach, *L. maderae*. The amount of enzyme

Fig. 1. Activity of guanase isolated from (a) adults, (b) symbionts; (c) nymphs, and incubated with guanine over a 2-h period

Fig. 2. Activity of guanase isolated from the symbionts and incubated with the substrate (a) xanthine, and (b) guanine over a 1-h period. This graph is identical with those obtained with the adult and nymphal extracts similarly treated.

extracted varied from time to time, and thus accounted for higher densities occasionally. Possibly the slightly lower values obtained when both substrates were incubated together with the enzyme can be accounted for in this fashion: the addition of the reaction product xanthine to the added substrate xanthine tended to shift the equilibrium of the reaction.

The 33.3 per cent lowering of the optical density of guanine by guanase over a 2-h period compares favourably with the 30 per cent decrease obtained by Lisa and Ludwig² with the fat body of the normal insect. Similarly, the R_F values of 0.030 and 0.087 obtained in these experiments for guanine and xanthine respectively also compare

Fig. 3. Disappearance of guanine and the simultaneous production of xanthine when the substrate was subjected to chromatographic studies, then eluted and assayed. (a) Activity of the symbiont enzyme; (b) activity of the adult enzyme; (c) activity of the nymphal enzyme.

favourably with the respective values of 0.000 and 0.062 obtained by those workers. However, the high activity obtained by these workers for the enzyme of the normal fat body could be attributed to the enzyme present in both the fat body and the symbionts. No difference in guanase activity was observed in the enzyme extracted from the symbionts or the adult fat body. However, the activity of the nymphal extract was much slower than that of the symbionts or adults. Possibly, the nymphs depend on the symbionts for guanase activity at some stage of their lives.

I thank Dr. Daniel Ludwig, of Fordham University, for his advice.

DIFFERENT MOLECULAR SPECIES OF MOUSE INTERFERON INDUCED BY STATOLON

By PROF. T. C. MERIGAN

Department of Medicine, Stanford University
School of Medicine, Palo Alto, California

DR. W. J. KLEINSCHMIDT

AND
Lilly Research Laboratories, Indianapolis,
Indiana

STATOLON, an anionic polysaccharide produced by *Penicillium stoloniferum*, achieves its antiviral action by stimulating interferon production, both in the whole animal and in tissue culture^{1,2}. The antiviral substance produced by chick embryo fibroblasts after statolon stimulation was demonstrated to be interferon by its host cell species specificity, acid stability, trypsin sensitivity, and a characteristic heat inactivation curve. Additional biological data suggesting the identity of the active portion of viral and statolon-induced interferons are provided by the experiments of Baron³. These showed that the *in vivo* antiviral protection with mouse interferon induced by statolon against three viruses (encephalomyocarditis virus, vesicular stomatitis virus, and vaccinia) is similar to that provided by the interferon induced by Newcastle disease virus (NDV). A number of other agents, including bacteria⁴, endotoxin^{5,6}, rickettsia⁷ and phytohaemagglutinin⁸, have also been reported to induce interferon production. The interferon produced by these non-viral agents has been characterized primarily by

biological methods. Viral-induced interferon, prepared *in vitro* or *in vivo*, has been shown to be indistinguishable for a given cell species⁹. In a particular species, completely unrelated viruses can induce formation of interferon that cannot be differentiated on the basis of biological and physical properties. In contrast, a single virus can be shown to induce the formation of physically different interferons in cells of different animal species⁹.

We have compared the characteristics of molecular size and charge of non-viral- versus viral-induced activities, as prepared both *in vitro* and *in vivo*. Mouse serum interferon was prepared by intravenous injection of mice with NDV (ref. 10). The serum was held at pH 2 for five days (4° C) to destroy residual virus. Chick interferon was prepared by influenza infection of 9–11 day embryonated eggs¹¹, and purified by zinc precipitation and 'CM-Sephadex' column chromatography¹². Statolon-induced mouse serum interferon was prepared by collecting serum from 12 to 14 g mice after statolon injections intraperitoneally of 2.5 mg or intravenously of 0.72 mg.

Table 1. APPEARANCE OF INTERFERON IN MICE AT DIFFERENT TIMES AFTER THE INJECTION OF STATOLON

Inhibition titre of serum pool (hours after injection)	Hours	Titre
	1	0
	2	258
	6	8,192
	12	4,096
	24	1,024
	48	128
	72	128

Appearance of interferon in mice at different times after the injection of statolon. Seven groups of 20 mice of 12–14 g were injected intravenously with 0.72 mg of statolon. The mice were bled at the times indicated after injection and the serum prepared. Interferon activity was measured by a plaque-inhibition of vesicular stomatitis virus on confluent monolayers of MCN cells. Titre is expressed as the reciprocal of the highest dilution of serum giving 100 per cent inhibition.

Weights of statolon used are based on the non-dialysable solids present in preparations prepared as described previously¹³. The time course of induction of interferon by intravenous administration of statolon in mice was determined (Table 1). For the mouse serum interferon used in these investigations, the mice were bled at 6 h following statolon injection. Statolon-induced interferon was prepared *in vitro* by applying 0.53 mg of statolon to a 6.5 × 13.5 cm monolayer of primary mouse embryo fibroblasts and collecting the supernatant fluids after 24 h. This interferon preparation was concentrated fifty-fold by dialysis against polyethylene glycol 6000 prior to use.

For estimation of interferon titre, a plaque-inhibition assay⁹ was used with a 50 per cent inhibition end-point. To minimize the antiviral effects produced by any residual statolon in the sample, short interferon adsorption periods (6 h) were used. After adsorption of interferon to confluent monolayers of primary mouse or chick embryo fibroblasts growing in tissue culture plates, the cells were challenged with vesicular stomatitis virus.

Mouse and chick interferons are highly specific for cell species^{9,14}. Because each could be assayed in the presence of the other, the method of co-chromatography⁹ previously used to compare viral-induced interferons was used. To determine the molecular weight of the various types of mouse interferon, chromatography was carried out on a long column of 'Sephadex G-100' using both standard chick interferon and phenol red as internal markers. The molecular weight of the statolon-induced mouse serum interferon was also determined by ultracentrifugation in a density gradient. Samples were centrifuged by the method of Martin and Ames¹⁵ in a 2–12 per cent sucrose concentration for 16 h at 105,000g in the Spinco SW 39 rotor, and position compared with that of an egg white lysozyme standard.

The polyacrylamide disc electrophoresis system of Ornstein and Davis¹⁶ was used for electrophoresis of interferon¹³, with the pH 4.3 acetate buffer of Reisfield¹⁷, and a methyl green internal standard. After electrophoresis, the gels were sliced into 1–2-mm sections and placed in tissue culture medium containing 0.05 per cent bovine serum albumin. They were eluted at 4° C overnight before assay of interferon activity in the individual aliquots of medium.

The statolon tissue culture mouse interferon had a molecular weight (Table 2) and electrophoretic mobility ($R_F = 0.35$) similar to mouse viral-induced interferon ($R_F = 0.35$). However, the statolon-induced interferon, as it appeared in mouse serum, had a greater molecular weight—approximately 90,000 (Fig. 1, Table 2). The electrophoretic migration of statolon-induced serum interferon ($R_F = 0.63$) is different from that of statolon-

Fig. 1. Molecular weight determination of various mouse serum interferons on 'Sephadex G-100'. Protein standards of known molecular weight were individually chromatographed on the same column. Chromatography of both interferon and protein standards was carried out at 4° C in phosphate-buffered saline on a 120 × 12 cm column of 'Sephadex G-100'. By this same method, Hallum, Stinebring and Youngner¹⁹ have demonstrated an identical molecular weight for NDV induced mouse plasma interferon which has not been exposed to pH 2 but which has had residual NDV virus inactivated by exposure to anti-NDV serum.

induced tissue culture interferon ($R_F = 0.35$). The sedimentation velocity of statolon-induced mouse serum interferon in a sucrose density gradient confirmed its high molecular weight (approximately 85,000). This differs from the value others¹⁸ have found for virus-induced mouse serum interferon (13,000–25,000).

Disaggregation of the heavy interferon was attempted with sodium dodecyl sulphate (SDS) (0.02 per cent), alkali (pH 11) and 5 M sodium chloride. Each was added to the serum by dialysing the sample at 4° C overnight against 50 vol. of the given reagent in 0.1 M salt. Before electrophoresis or chromatography, the reagents were removed by dialysis against 50 vol. of buffer appropriate for the electrophoretic or chromatographic procedure. Unfortunately, the SDS destroyed the activity of the statolon-induced mouse serum interferon. The electrophoretic migration of statolon serum interferon was not influenced by exposure to pH 11 ($R_F = 0.61$) or the 5 M sodium chloride ($R_F = 0.68$).

Previous investigations¹² demonstrate viral-induced chick interferon to be a covalently bonded structure of molecular weight about 30,000 and slightly acidic in charge. It has disulphide bridges, though the number of polypeptide chains is unknown^{12,20}. The viral-induced interferons of chick, mouse and man all have a similar molecular weight and charge¹². The molecular weights have been determined by both sucrose density gradient ultracentrifugation and 'Sephadex G-100' column chromatography^{11,12,18,21–23}. Mouse and chick interferons have indistinguishable charges by gradient ion exchange co-chromatography on 'CM-Sephadex'. Chick, mouse and human interferons are eluted from the 'Amberlite XE-64' resin over the same pH range, whether prepared *in vivo* or in tissue culture¹². For example, human interferon induced in tissue culture by Newcastle disease virus chromatographically resembles human serum interferon induced during immunization with live measles vaccine²⁴.

Table 2. MOLECULAR WEIGHT ON 'SEPHADAX G-100' OF VARIOUS MOUSE INTERFERONS

Type	Inducing agent	Molecular weight
Tissue culture interferon	Chikungunya virus	28,000
Serum interferon	Newcastle disease virus	28,000
Tissue culture interferon	Statolon	34,000
Serum interferon	Statolon	90,000

Comparison of molecular weights of various interferons as determined on 'Sephadex G-100'.

Mouse ($R_F = 0.35$), chick ($R_F = 0.29$) and human ($R_F = 0.32$) interferon all have relatively similar electrophoretic migrations with respect to a methyl green marker¹², in polyacrylamide gels at pH 4.3. The charge and size properties of mouse interferon induced in primary mouse embryo fibroblasts by statolon resemble those of viral-induced interferons.

On the other hand, statolon mouse serum interferon has both different size and charge characteristics. It appears to be similar to the endotoxin-induced heavy mouse interferon described by Hallum, Stinebring and Youngner¹⁹. Statolon differs from endotoxin in its relative lack of toxicity and higher potency of *in vivo* antiviral activity²⁵.

The fact that interferon induced in tissue culture by statolon is similar to viral-induced interferon in both charge and size suggests that interferon induced *in vivo* by statolon is an aggregated form of the smaller molecule. This association could occur either by polymerization with itself or by aggregation or covalent bonding to another molecule. It is possible that the two activities reside in entirely unrelated molecules.

Schonne²⁶ has observed that Sindbis virus in tissue culture stimulates the production of rat interferon, with a molecular weight range of 29,000–100,000. Others^{27,28} have noted viral interferons to form complexes with bovine serum albumin: hence procedures known to break up protein complexes might demonstrate the structural identity of *in vivo* and *in vitro* statolon-induced interferon. In contrast with chick interferon¹², both statolon and viral-induced mouse interferons are inactivated by high concentrations of urea. Therefore, they cannot be investigated with electrophoretic procedures in urea-containing buffers which have been successfully used with chick interferon¹².

Although *in vivo* statolon-induced interferon is similar to that induced by endotoxin in molecular weight and charge, the time of appearance of circulating interferon after injection of statolon is different from that seen with endotoxin (Table 1). The interferon induced by endotoxin had a peak titre at 2 h and had virtually disappeared at 24 h (ref. 5). The time pattern of appearance of statolon-induced interferon is similar to the pattern observed with viral-induced interferon, with the highest titre occurring at 5 h (ref. 10) or at 12 h (ref. 4).

In summary, statolon-induced mouse serum interferon was found to differ from virus-induced mouse interferon in molecular size and charge. The significantly higher molecular weight (90,000) of the former was observed with both 'Sephadex G-100' column chromatography and sucrose density ultracentrifugation. The mouse interferon induced by statolon in tissue culture, however, resembled the viral-induced interferon in molecular weight (30,000) and in electrophoretic mobility in polyacrylamide gels.

AUTORADIOGRAPHIC IDENTIFICATION OF THE D (13–15) CHROMOSOME RESPONSIBLE FOR D₁ TRISOMIC PATAU'S SYNDROME

By DR. F. GIANNELLI

Paediatric Research Unit, Guy's Hospital Medical School, London, S.E.1

IT has recently been shown that the pattern of DNA synthesis of human chromosomes is complex and appears to be relatively chromosome specific, but the mechanism responsible for the time sequence of chromosome synthetic events is unknown.

This article reports an investigation of the labelling patterns of the D group chromosomes based on a case of Patau's syndrome, which is known to be a D₁ interchange trisomic.

The patient (PRU No. 1492), a girl who died in the neonatal period, was considered in life and at necropsy to have the typical features of Patau's syndrome generally caused by primary D₁ trisomy¹.

Blood and skin cultures were analysed in the Paediatric Research Unit by Dr. A. I. Taylor. Forty-five cells were counted and the modal number was 46. Formally, one D (13–15 Denver) chromosome was missing and an extra chromosome resembling a No. 3 was present. In the light of the clinical findings, the patient was thought to be a case of interchange D₁ trisomy, and it was considered likely that two chromosomes of the D group were involved in the interchange, or else that the additional chromosome

resembling a No. 3 was an isochromosome of the long arm of a D chromosome. An additional 156 complete metaphases were analysed; each contained 46 chromosomes and showed the chromosome complement already described here. Cytological analysis of the patient's parents showed that they had normal chromosome complements.

Blood, cultured by a micromethod developed in this Unit², was labelled by adding 0.25 μ c. of tritiated thymidine (Radiochemical Centre, Amersham, spec. act. 2 c./mmole) to each ml. of culture for the last 4 h of incubation, so as to differentially label the very late synthesizing chromosome regions. Desacetylmethylcholchicine ('Colcemid', Ciba) was added 1.5 h prior to termination.

Skin cultures were set up by the technique described by Hsu and Kellog³ and labelled at the third passage by adding 0.25 μ c. of tritiated thymidine (Amersham, spec. act. 2 c./mmole) to each ml. of culture medium for the last 7 h of incubation, and treated with 'Colcemid' for the last 3 h. Slides were prepared by air drying.

Autoradiographs of blood culture slides were prepared at once by a stripping film technique⁴, but skin culture slides were first stained for 3 min in 2 per cent lacto-

acetic orcein and well-spread metaphases were photographed. Then the slides were rinsed in several changes of xylol and absolute alcohol, hydrolysed for 2 min in 4 N hydrochloric acid at 18° C and coated with Kodak 'AR 10' autoradiographic stripping film. After exposure for 5 days, they were developed and stained with azurmethylen-blue⁵.

Qualitative analysis of DNA labelling patterns. The accuracy of the results of the examination of chromosome labelling patterns is limited by, among other factors, the random nature of tritium radiations and by the resolution of the available autoradiographic techniques. Therefore, errors of classification based on single cells are likely to occur and the pairing of morphologically similar chromosomes requires a statistical approach which involves the analysis of numerous individual cells. In this study, in order to avoid bias, each of the chromosomes under consideration has been given a letter code according to its labelling pattern and only in the final conclusions have these patterns been related to the different chromosome pairs.

Blood cultures were used to give information on the very last part of the chromosome DNA synthesis and skin cultures to examine a longer period of DNA synthesis and try to resolve more clearly the differences in the synthetic patterns of the *D* group chromosomes.

(A) **Labelling patterns of the *D* group chromosomes.** In blood culture the five *D* chromosomes showed three labelling patterns (Fig. 1): the first (coded type *A*) was marked by a pattern of dense labelling of the distal part of the long arm, while the proximal part of the long arm and the centromere were unlabelled; the second (type *B*) showed diffuse labelling, which was often denser over the proximal part of the long arm and the centromere; and the third (type *C*) was unlabelled or had less than five autoradiographic grains per chromosome.

The *D* chromosomes in the skin cultures were distinguished as follows: type *A*¹ either completely labelled or with a small unlabelled gap in the long arm near the centromere, or with short arm and centromere region unlabelled; type *B*¹ with dense labelling over the centromere region and proximal half to two-thirds of the long arm; type *C*¹ with the short arm and centromere labelled but with the long arm almost completely unlabelled (Fig. 1). The difference between the *B*¹ and *C*¹ types was more quantitative than qualitative. At times one or more *D* chromosomes showed only few randomly scattered auto-

Table 1. CELL DISTRIBUTION IN RELATION TO THE LABELLING PATTERNS OF THE *D* CHROMOSOMES

radiographic grains. This is considered to be a pattern equivalent to a *C*¹ type in cells which became exposed to tritiated thymidine late in the DNA synthetic period and we will refer to this pattern as *C*². The cell distribution according to the labelling patterns of the *D* chromosomes is shown in Table 1.

(B) **Labelling patterns of the large metacentric chromosomes resembling No. 3.** In blood culture, two out of the three large metacentric chromosomes resembling chromosome No. 3 (Denver) showed a diffuse light labelling over both arms, often with a dense cluster of autoradiographic grains over the centromere region (type *Z*). By contrast the third metacentric chromosome (type *A/A*) showed heavy and symmetrical labelling over the distal part of both arms while the centromere region was generally unlabelled.

In skin cultures these large metacentric chromosomes were usually completely labelled, but two had denser labelling of the centromere and sometimes lighter labelling of the middle part of one or both arms (type *Z*¹), while the third had a lightly labelled centromere region (type *A*¹/A¹) (Fig. 1). The cell distribution relative to the labelling patterns of these chromosomes is shown in Table 2.

Quantitative analysis of DNA labelling. In the experiments recorded here the labelling pattern of a chromosome is related to the position of the late synthesizing regions, while the number of autoradiographic grains is a function of the number, size and rate of DNA synthesis, of the late synthesizing regions. Therefore, the grain count has been used to distinguish further between the different *D* group chromosomes, to separate the normal chromosomes No. 3 from the morphologically similar *D/D* chromosome, and to examine its structure. In blood culture, the mean grain count over the type *A/A* chromosome has been compared with that over the two of type *Z* and the mean of half the grain count over the type *A/A* with the mean grain count of the type *A* chromosome and the most densely labelled non-*A/D* chromosome (hot-non-*A*). The *A* and hot-non-*A* chromosomes were also

Bold type (for example, A/A) signifies the mean grain count over the relevant chromosomes (for symbols of these, see text). $X = 7.5$ per cent of the grains counted over the A type D chromosome.

compared between themselves. In the skin culture similar comparisons were made. The findings are summarized in Table 3.

Because of asynchrony of cellular DNA synthesis, it was decided to standardize the grain counts over each arm of the A/A or A^1/A^1 type metacentric chromosome and the D group. This was done as follows:

In each cell the counts over each arm of the A/A and A^1/A^1 type chromosome and the D chromosomes were multiplied by a factor obtained by dividing the mean grain count of each chromosome group for all the cells by the grains counted over the corresponding group in each individual cell. In this way the counts for each chromosome are adjusted relative to the group's total counts and comparison is thus made possible. For this analysis only the D chromosomes of 82 skin culture cells (where grains could be counted with sufficient accuracy) were used. Blood culture cells had far too many unlabelled chromosomes and were, therefore, discarded. The chromosomes of the D group were classified in each cell according to their grain counts. Then the frequency distribution curves of the adjusted grain counts over both arms of the A/A and A^1/A^1 chromosome and of all the five D chromosome classes were plotted (Figs. 2 and 3).

Conclusion and discussion. Two of the three large metacentric chromosomes (type Z or Z^1) completed DNA synthesis first in the median part of one or both their arms, then in the terminal parts of both arms and finally in the centromere region, and have been interpreted as the normal pair No. 3, known to have a similar synthetic pattern^{6,7}. The third metacentric chromosome (A/A or A^1/A^1) showed a very symmetrical pattern of DNA synthesis; the centromere and the proximal part of each arm completed their DNA synthesis early while the middle and distal parts did so late. This chromosome was interpreted as the D/D chromosome. Consistently, only one A (or A^1) type chromosome was present in the patient's cells and it had a pattern of DNA synthesis similar to that of each arm of the presumptive D/D chromosome and markedly different from the remaining four D chromosomes. A small region of the long arm of this type A element, near the centromere, was the first to complete synthesis followed by the centromere and short-arm region, while the middle and distal parts of the long arm synthesized their DNA very late. The other four

D chromosomes, in those cells in which only one D chromosome of type A was present, could be classified into two different pairs (B or B^1 , and C or C^1 or C^2), according to their labelling patterns. These differences, however, were not invariably clear enough to allow confidence in the precise allocation of these four chromosomes. There was an excess of type C chromosomes, particularly in blood cultures, because this type includes a pair of early synthesizing D chromosomes (type C proper) plus all the unlabelled or weakly labelled D chromosomes belonging to

Fig. 2. Adjusted grain counts frequency distribution of the two arms of the A/A and A^1/A^1 type metacentric chromosome

Fig. 3. Adjusted grain counts frequency distribution of the D chromosomes

the other two types found in those cells which had almost completed DNA synthesis before tritiated thymidine was added to the cultures. All four non-*AD* group chromosomes had a similar sequence of synthetic events, but one pair (*C*, *C*¹ or *C*²) was often ahead of the other pair (*B* or *B*¹) in its DNA synthesis. These all completed DNA synthesis first in the distal part of the long arm, then in the proximal part, centromere and short-arm regions, and were interpreted as two pairs of homologous chromosomes with some degree of intrapair asynchrony which was thought to contribute to the blurring of the difference in their DNA synthesis. The labelling over the short arms of these chromosomes was much denser in the skin culture than in the blood culture. This is probably due to the different periods of time for which the cells in the two tissues were exposed to tritiated thymidine but a specific tissue difference is not excluded.

The grain count analysis showed that in the fraction of the DNA synthetic period studied in blood and skin cultures, the two presumptive No. 3 chromosomes synthesized a significantly smaller amount of DNA than the presumptive *D/D* chromosome (Table 3: 1 and 5), thus confirming the distinction made on the basis of the labelling patterns. The *D* chromosome of the *A* or *A*¹ type synthesized significantly more DNA than any of the other *D* chromosomes (Table 3: 4 and 10). The frequency distribution of the adjusted grain counts of the two arms of the *D/D* chromosome did not show any sign of bimodality (Fig. 2). Therefore, the mean grain counts over each of these two arms should not be greatly different from each other, and the results in Table 3: 2 and 3 and 7 and 9 (see following) can be taken as evidence that in blood cultures each arm of the *D/D* chromosome synthesized an amount of DNA equal to that synthesized by the *A* or *A*¹ group chromosome and significantly higher than that synthesized by any of the other *D* chromosomes.

While, as indicated, in blood cultures the *A* type *D* chromosome had completed DNA synthesis in the region of the short arm and centromere, in skin cultures the *A*¹ type was often still synthesizing DNA in this zone. The grains counted over this part of the chromosome were 15 per cent of the total count over the same chromosome. Since the *D/D* chromosome is at least without short arm and centromere region of one of the *D* chromosomes which form it (assuming that it is the result of an interchange), it is not surprising that, in contrast to the observations made on blood cultures, in skin cultures the mean of half the grain counts of the presumptive *D/D* chromosome was significantly smaller than the mean grain count over the *A*¹ type *D* chromosome (Table 3: 6) and was not significantly larger than the mean grain count over the hot-non-*A* type *D* chromosome (Table 3: 8). However, if 7.5 per cent of the counts over the *A*¹ type *D* chromosome is added to half the grain counts of the presumptive *D/D* chromosome to account for the loss of one short arm and centromere region, the skin culture findings are similar to those in blood cultures (Table 3: 7 and 9).

Finally, the five frequency distribution curves of the adjusted grain counts of the *D* chromosomes fall quite clearly into three groups (Fig. 3): two curves with low mean grain counts, two curves with intermediate mean grain counts, and only one curve with high mean grain count. Type *C*¹ and *C*² chromosomes contributed mainly to the first and second curve, type *B*¹ to the third and fourth, and type *A*¹ almost exclusively to the fifth curve. Therefore, I feel justified in dividing the five normal *D* chromosomes present in this patient into one late replicating chromosome, two intermediate replicating and two early replicating chromosomes, having respectively type *A*¹, *B*¹ and *C*¹ or *C*² labelling patterns.

The *D/D* chromosome has both arms with a labelling pattern and grain count very similar to the *A* type *D* chromosome, and this suggests either that it is formed by the union of two homologous *A* type *D* chromosomes or that it is an isochromosome for the long arm of this

chromosome. In either event, the patient would be effectively trisomic for the type *A* chromosome. However, it could be argued that the interchange chromosome, if this is indeed what the *D/D* chromosome is, is formed by two non-homologous *D* chromosomes and one of them carries factors capable of inducing a new pattern of DNA synthesis in the other. This is in contrast with our experience in other autosomal interchanges of similar type^{8,9}. Moreover, the complex pattern of human chromosome DNA synthesis suggests that it is controlled perhaps by more than one factor influencing discrete chromosome regions and it seems to us unlikely, therefore, that in an interchange of the centric fusion type between two non-homologous chromosomes, one of them could control the pattern of synthesis of the other. Finally, if the *D/D* chromosome were formed by non-homologous chromosomes, one being a type *A* and the other a type *B* or *C*, the patient would be trisomic for one of the latter chromosomes because he carries already two normal type *B* or *C* chromosomes. This would be in contrast with the clinical description and our findings in a primary *D*₁ trisomic subject with Patau's syndrome in whom three *A* type *D* chromosomes were present¹⁰, and with two similar cases reported by Yunis *et al.*¹¹, where again three *A* type *D* chromosomes were found.

The suggestion has been put forward⁷ that in trisomics one of the chromosomes present in triplicate might be delayed in its DNA synthesis. Our findings in this patient and in one primary *D*₁ trisomic subject¹⁰ indicate a great similarity in the pattern of DNA synthesis and a fair degree of synchrony between the three presumptive homologues.

The chromosomes responsible for *D*₁ trisomy have large late synthesizing regions^{10,11} and the same may be true of the chromosome responsible for *E*₁ trisomy^{12,13} and Down's syndrome^{7,14}. Late DNA synthesis in the *X* chromosome has been correlated with genetic inactivation. Yunis¹⁵ and Stalder *et al.*¹⁶ have suggested that the viability of the *D*₁, *E*₁ and perhaps 21 trisomic zygotes is due to the presence of large late synthesizing and, by inference, genetically inert chromosome regions. However, this functional interpretation of the patterns of autosome DNA synthesis is a matter of conjecture based on analogy with the late synthesizing *X* chromosome which may not apply to the autosomes. In fact, late autosome DNA synthesis is concordant in all members of a chromosome pair while one *X* chromosome does not show late synthesis and is always out of step with the other (or the others). Therefore, while the idea of the relative genetic inertness of the autosomal late synthesizing regions is tempting, direct genetic evidence is wanted to attempt safely a functional interpretation of the autosomal patterns of DNA synthesis. On the grounds of these results, it is clear that what I have called *A* type *D* chromosome is responsible for *D*₁ trisomy and that the pattern of DNA synthesis is not altered by the trisomic state.

I thank Prof. P. E. Polani and Mr. J. L. Hamerton for their advice, Dr. J. A. Fraser Roberts for his advice on the statistical treatment of the data, Miss D. A. Baker for the illustrations, and Miss V. M. McGuire, Miss G. Olley, Mrs. B. Scott and Mr. E. Nicholson for their assistance. This work was supported by the Spastics Society.

ASTROPHYSICS

Measured Velocities of Interplanetary Dust Particles

An interplanetary dust particle experiment was flown on the *OGO-I* satellite launched in September 1964. The primary purpose of the experiment was to measure the speeds and directions of arrival of dust particles within 120,000 km of the Earth's surface, and thus determine the orbits of these particles. If sufficient orbits had been measured, the nature of the apparent dust cloud around the Earth¹ could have been determined. Troubles were encountered with both the spacecraft and the experiment, however, and only three probable dust particle impacts were recorded. This communication briefly describes the instrument and the limited amount of results obtained.

The detector array consists of four tubular detectors aligned along the three body axes of the spacecraft. One detector looks radially away from Earth ($-Z$ direction) and the other three look in a plane normal to the Z direction. Each detector accepts particles with an apparent radiant not more than 6° removed from the detector axis (Fig. 1). An impacting micrometeoroid first encounters the front thin-film sensor which comprises two thin films and a grid. The plasma generated by the passage of the particle through these films starts a 2 mc/s clock which is stopped when the particle impacts on the rear sensor 10 cm down the tube. Thus, the time of flight over 10 cm is measured and the particle velocity following the penetration of the front sensors is determined. The deceleration suffered by a 10^{-10} g iron particle passing through the front sensor at speeds around 3 km/sec has been experimentally determined to be about 10 per cent.

The rear sensor performs two main functions. First, there is a thin-film capacitor deposited on a glass plate. This capacitor momentarily shorts when a particle impacts and the resultant signal stops the time-of-flight clock. Second, a lead zirconate transducer bonded to the back of each glass plate provides a measure of the momentum of each impacting particle. Knowing the velocity, the particle mass can be determined. Thus each tubular detector can provide a measure of the velocity, direction of arrival, and mass of an impacting dust particle.

Three particle impacts were recorded on one tube during the first ten days of operation. Spacecraft trouble was such that the experiment was only turned on for 56 h of this time, and data were received for only 4 h of these 56. Unfortunately, the rear sensor capacitors can suffer a permanent short when subjected to particle impact with the power off the experiment. There was no provision for clearing such a short on this particular experiment, and we believe that three of the four capacitors were dead before experiment data were received. The experiment

was again turned off for a short period after the third impact had been recorded, and although a great quantity of data has been received since, no more impacts have been noted. This suggests that the fourth sensor was shorted by impact when the experiment was turned off on the tenth day after launch.

In view of the paucity of data (the three impacts total only ten bits of information with no redundancy) we had to look rather closely into the statistical reality of the data, considering both experiment noise and telemetry noise. There is no history of the former in our experience with the instrument flown. The unit is well shielded electrically, and also, a time-of-flight measurement requires two independent events to occur within a very restricted time-interval. There were no spacecraft commands sent at the time of the three events, nor did the neighbouring telemetry words show any signs of radio-frequency interference. We have considered the possibility of telemetry noise indicating false impacts and treated the first three weeks of data in considerable detail. The probability of all three impacts being false is less than 2 parts in 10^5 , and the probability of any two of the three being false is less than 3 parts in 10^3 .

The details of the three impacts are shown in Table 1. The first two were recorded within 27 min of each other at altitudes in excess of several Earth-radii, and the observed velocities were in the range 30–50 km/sec. These velocities preclude any possibility that the particles were in closed orbits around the Earth. The third impact indicates a low-velocity particle which impacted at a much lower altitude and which may have had a mass of an order of magnitude greater than the masses of the first two.

Table 1. IMPACT PARAMETERS OF PARTICLES OBSERVED BY THE COSMIC DUST EXPERIMENT ON *OGO-I*

	Time of impact (U.T. 1964)	Altitude (km)	Observed velocity (km/sec)	Geocentric velocity (km/sec)	Mass (g)
Hit 1	257 ^d 03h 45 ^m	22,400 km	$40 < V_0 < 50$	$40 < V_g < 70$	$< 7 \times 10^{-13}$
Hit 2	257 ^d 04h 12 ^m	28,700 km	$33 < V_0 < 40$	$30 < V_g < 60$	$< 1 \times 10^{-11}$
Hit 3	259 ^d 18h 35 ^m	2,900 km	$4.7 < V_0 < 4.8$	$8 < V_g < 15$	$< 7 \times 10^{-11}$

The uncertainty in the observed velocity arises partly from the necessity to digitize the time of flight for telemetry and partly from the uncertainty in the actual deceleration through the front sensor. The maximum deceleration allowed in computing the possible geocentric velocities was 30 per cent. The attitude of the spacecraft at the times of the three impacts was unfortunately not known, so that the range of geocentric velocities possible for each impact was broadened even further to the values given in Table 1. Even with the true geocentric velocities being subject to such wide limits and with only the spin axis of the spacecraft known, it has been possible to deduce something about the probable orbits of these three particles before impact. The first two were probably in high-eccentricity heliocentric orbits of high inclination to the ecliptic plane; in fact the orbits were probably retrograde. For masses less than 10^{-11} g, one would not expect the particles to remain in these orbits for periods much greater than 10^3 or 10^4 years, so probably they were of relatively recent origin, perhaps from a long-period comet. It is worth noting that the direction of the spin axis of the spacecraft precludes any possibility that the two high-speed particles came from the Moon. They must have been in heliocentric orbits.

The third particle could have been either in a closed geocentric orbit or in a low eccentricity orbit of low inclination. The lack of spacecraft attitude information prevents any further delineation. Finally, the flux based

Fig. 1. The *OGO-I* micrometeoroid sensor which determines particle mass and velocity

on these three impacts in 4 h is in excellent agreement with the microphone data recorded by previous near-Earth satellites².

PHYSICS

A Dense Packing of Hard Spheres with Five-fold Symmetry

SUPPOSE a plane of hard spheres is constructed such that the spheres form concentric pentagons with an odd number of balls per pentagon side. A second plane of hard spheres is now constructed such that the spheres form concentric pentagons with an even number of spheres per pentagon side. If this second plane is placed in intimate contact with the first, with their five-fold axes coincident, there results a layer which, within the plane of the layer, can be continuously packed to infinity (Fig. 1). Identical layers can then be stacked one on another, with their five-fold axes coincident, to give an infinite packing along the five-fold axis. An infinite structure can thus be constructed the nucleus of which is a pentagonal dipyrmaid of seven spheres.

Following the foregoing packing sequence with polygons other than the pentagon results in other, well-known structures. The same sequence with squares yields cubic close packing¹ and, with hexagons, primitive hexagonal. A difficulty arises when attempts are made to apply the exact sequence to triangles, because concentric triangles with an even (or odd) number of spheres per side cannot be made coplanar. It is important that, of these polygons, only the pentagon cannot form a regular tessellation and therefore, although it can be packed to infinity, it has a unique axis, the single five-fold rotation axis.

Fig. 1. A layer of hard spheres based on a packing sequence of concentric pentagons.

An alternative way of generating the same pentagonal structure is as follows: Construct $n(n = 1, 2, 3, \dots \infty)$ pentagonal pyramidal shells of hard spheres such that each face is an equilateral triangle of side length n (spheres). If shell 1 is placed in the cavity of shell 2 there results a pentagonal dipyrmaid of seven atoms. Likewise when shell 3 is placed on the structure there results a pentagonal dipyrmaid of twenty-three spheres. In fact, as each subsequent shell is placed on the growing structure there always results a pentagonal dipyrmaid bounded by close-packed planes, each face of which is an equilateral triangle with n (shell number) spheres to a side. This pentagonal dipyrmaid consists of five distorted tetrahedral the edges parallel to the five-fold axis being expanded by 5.15 per cent. Within each tetrahedron the structure is body-centred orthorhombic with cell dimensions chosen such that the pentagonal dipyrmaid faces will be close packed and two adjacent tetrahedra will be joined by a coincidence boundary. These conditions yield a body-centred orthorhombic cell with dimensions (diameter of sphere = 1.000), $a = 1.000$, $b = \cot 36^\circ = 1.3764$, $c = (2^2 - \csc^2 36^\circ)^{1/2} = 1.0515$. Thus this pentagonal structure has a density independent of position of 0.72357. This density is slightly lower than that for close packing (0.74048), but higher than body-centred cubic (0.68017) or icosahedral shell packing (0.68818) (ref. 2). The co-ordination is 10 at a distance of 1.000 and 12 at a distance of 1.052. This structure is an example of G_2^1 type symmetry, that is, a one-dimensionally periodic group in three dimensions, and its symmetry group is $5mP2ml$ (Niggli's³ nomenclature).

Structures which have the symmetry described here have been observed experimentally. Gedwill, Altstetter and Wayman⁴, using optical microscopy, observed five-fold symmetry in cobalt crystals produced by the hydrogen reduction of cobaltous bromide. Wentorf⁵, also using optical microscopy (external morphology), observed five-fold symmetry in synthetic diamonds. Ogburn, Paretskin and Peiser⁶, using X-rays, found pentagonal symmetry in copper [110] dendrites grown by electrodeposition. The most striking examples, however, are the sub-micron whiskers of nickel, iron and platinum grown from the vapour by Melmed and Hayward⁷. These whiskers, 50–200 Å in diameter, had a five-fold rotational symmetry observed by field emission microscopy. The five-fold symmetry was found not to be limited to the surface, as no change in symmetry was observed in the continuous reduction in length of several iron whiskers.

In all these cases the structure was explained as a quintuple twin ((111) twinning plane) with five face-centred cubic individual crystals about a common [110] axis, the $7^\circ 20'$ difference between $5 \times 70^\circ 32'$ and 360° being made up with lattice strain or imperfections. It is unlikely, however, that a twinning mechanism could generate a structure having the small size (50–200 Å) and atomic perfection (at the five-fold axis) of Melmed and Hayward's⁷ whiskers. On the other hand, it appears that the formation of a pentagonal dipyrmaid nucleus and its subsequent growth is a more probable and simpler mechanism for the formation of this structure. Furthermore, if a twinning mechanism were responsible for the five-fold symmetry one would expect [110] to be an observed whisker orientation in normal, non-pentagonal, whiskers. This is indeed the case for nickel and platinum, but the observed orientation for face-centred cubic iron is [100] (ref. 8).

It is also to be noted that the pentagonal nucleus for the structure described here has the same form as one of the configurations which has been proposed as an important element of liquid structure by Bernal^{9,10}. It is evident from the foregoing discussion that crystallization can occur by the growth of such a configuration.

GEOFYSICS

Damping of S Waves

THE modified Lomnitz law of imperfection of elasticity makes the strain under constant stress P :

$$\epsilon = \frac{P}{\mu} \left[1 + \frac{q}{\alpha} \{ (1 + at)^\alpha - 1 \} \right] \quad (1)$$

α is probably such that at is large for $t = 1$ second. For longer times the relevant constants are the rigidity μ , α , and qa^α . The data used to estimate α and qa^α are the damping of the 14-monthly variation of latitude and the fact that S at a distance of about 80° is clear and attains half the value for pure elasticity in about 2 sec. An alternative, possibly better, is to take the ratio as $\frac{1}{2}$. These lead to estimates as follows¹:

I	α	$10^4 qa^\alpha \times (1 \text{ sec})^\alpha$	
$\frac{1}{2}$	0.256	3.247	(1)
$\frac{1}{4}$	0.236	4.415	

These lead to no contradictions with other data, such as have been found in attempts to apply the elasto-viscous law. Since estimates of damping have now been made from surface waves, it appears interesting to compare the results with those found from the foregoing law. In this communication values are found for S waves.

The exponent in the complex representation of a travelling harmonic wave is:

$$zt - \frac{zx}{\beta_0} - \frac{1}{2} \frac{qx}{\beta_0} (\alpha - 1)! a^\alpha z^{1-\alpha} \quad (2)$$

where z is to be taken as imaginary. With $z = i\gamma$, $\gamma > 0$, this is:

$$\begin{aligned} & i\gamma \left(t - \frac{x}{\beta_0} \right) - \frac{1}{2} \frac{qx}{\beta_0} (\alpha - 1)! a^\alpha \gamma^{1-\alpha} e^{\frac{1}{2}\pi i(1-\alpha)} \\ &= i \left[\gamma \left(t - \frac{x}{\beta_0} \right) - \frac{1}{2} \frac{qx}{\beta_0} (\alpha - 1)! a^\alpha \gamma^{1-\alpha} \sin \frac{1}{2}\pi(1-\alpha) \right] \quad (3) \\ & \quad - \frac{1}{2} q \frac{x}{\beta_0} (\alpha - 1)! a^\alpha \gamma^{1-\alpha} \cos \frac{1}{2}\pi(1-\alpha) \end{aligned}$$

For $z = -i\gamma$ the imaginary part is reversed and the real part unaltered. The latter gives a damping, with exponent proportional to the distance travelled.

In the calculations the travel time x/β_0 was taken as 200 sec, corresponding to a distance for S of about 7° . The real part of the exponent is denoted by $-k$, and results are given for different periods of the wave, $2\pi/\gamma$, in sec.

Period	k	
	$\alpha = 0.256$	$\alpha = 0.236$
1	0.176	0.251
2	0.105	0.148
5	0.053	0.073
10	0.032	0.043
20	0.019	0.025
50	0.0086	0.013
100	0.0057	0.0074
1,000	0.0010	0.0013

For distance 20° these must be multiplied by nearly 3. But it is clear that the results do not account for the fluctuations of amplitude in S (or in P) at distances up to 20° , by factors of order 100. 5 sec can be regarded as a typical period of the first swing. I should expect results for surface waves to be comparable.

The data used sample the whole of the Earth's shell (now, rather unfortunately I think, usually called the mantle) and therefore refer to average properties. We should like to know to what extent they refer to the outer tenth of the radius. The amplitudes of both P and S decrease greatly to about 10° and rise to strong maxima about 20° . This has been attributed alternatively to variation in the rate of change of velocity with depth and to absorption; these could both produce similar effects on amplitudes. It seems that if the average imperfection of the shell is applicable to the outer tenth absorption is inadequate. Conversely, if the variations of amplitude in earthquake waves are attributed to absorption, this must be in a very thin layer.

The additional imaginary part of the exponent in equation (3) would imply a delay in travel time, proportional to $(\text{period})^\alpha$, and therefore would have little effect for short periods.

The calculations in this communication were made by Miss A. A. Houston at the Mathematical Laboratory, Cambridge.

Estimates of damping of free oscillations are given by Alsop, Sutton and Ewing², in the form:

$$A(t) = A(t_0) \exp \left[- \frac{\pi(t-t_0)}{QT} \right] \quad (4)$$

For the ${}_0S_2$ node they give the period T as 53 min, $Q = 370$. As this mode affects all the shell it should be comparable with the foregoing, with x about 3,000 km, and the expected damping coefficient would be of order 5×10^{-3} . Thus their value is of the order that would be expected from this rough comparison.

Cassiterite as a Carrier of Palaeomagnetism

IN an attempt to extend the scope of palaeomagnetism when investigating endogenous geological processes^{1,2} the magnetic properties of high-temperature minerals were investigated. The main objective was to find other minerals not yet examined from this point of view which would be amenable to palaeomagnetic examination. The Japanese work on synthetic ferrites³ suggested to us that certain natural high-temperature minerals (possessing a high isomorphic miscibility of elements) might have similar lattice structures and in consequence be ferromagnetic and capable of retaining a stable thermoremanent magnetization. The investigation proved successful. Garnets were the obvious minerals for initial examination. All the garnets examined possessed a weak ferromagnetic moment of the order 10^{-5} E.M.U./c.c., but were found to be unstable and so of little use in palaeomagnetism. Of a number of other minerals examined, cassiterite was found to possess unique palaeomagnetic properties.

Cassiterites obtained from Czechoslovakia (Horní Slavkov, Cínovec), as well as foreign localities (Cornwall, south-west England, Altenberg, Eastern Germany, Swaziland, the Congo, Mexico and New England), showed values of natural remanent magnetization (J_n) ranging from 10^{-7} to 10^{-3} E.M.U./c.c. Of a total of 44 samples examined, 18 had values of J_n lying between 10^{-4} and 10^{-3} E.M.U./c.c., which are values comparable to those exhibited, for example, by Central European basalts.

Fig. 1. Stereographic projection of J_n directions of oriented samples of the greisen body 'Huber', Horní Slavkov. ●, ○, Projection of the J_n direction into the lower and upper hemispheres; —•—, projection of the mean direction of J_n ; ★, direction of the present-day theoretical dipole field. Left-hand side: mean J_n directions and confidence circles calculated at the probability level of 95 per cent⁴ for samples collected at three distance localities of the same worked deposit (Nos. 2, 3 and 4); No. 1 stands for the mean direction and confidence circle for all measurements. Right-hand side: projection of J_n direction of all the greisen samples investigated, the mean direction and corresponding confidence circle

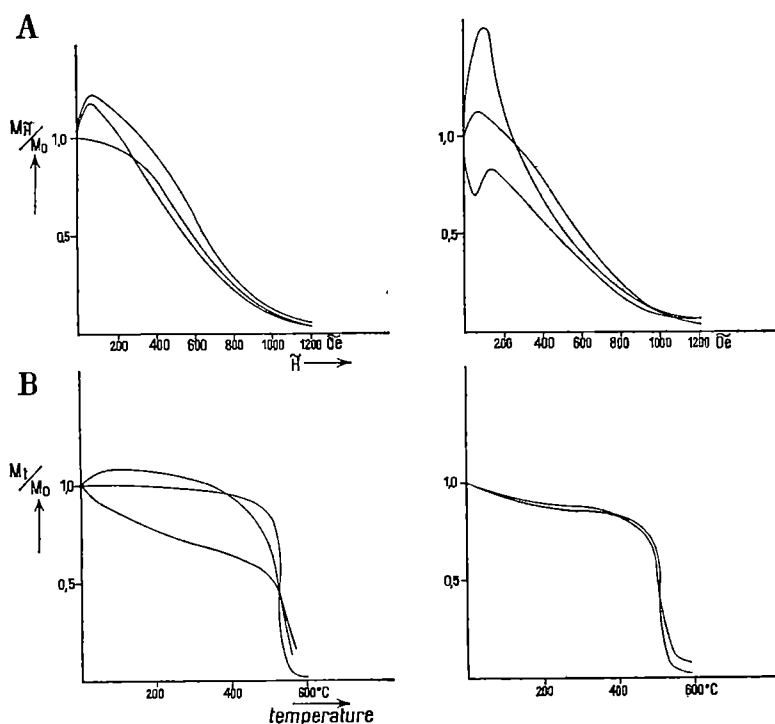

Fig. 2. a.c. (A) and thermal (B) demagnetization of greisen samples, the J_n directions of which are shown in Fig. 1. M_n , Magnetic moment of a sample demagnetized by an H field (oersted); M_t , magnetic moment of a sample demagnetized at temperature t (in centigrade); M_0 , natural magnetic moment

Another characteristic of all the cassiterites is their high Q_n -coefficient (the ratio of remanent to inductive magnetization measured in the Earth's magnetic field) which is usually of the order of 10^1 and frequently is greater than 50. In the course of a.c. demagnetization the direction of remanent magnetization did not change significantly from the J_n direction and only in strong fields (1,200 oersted) did the magnetic moment drop to 2–20 per cent of its original value. A similar resistance was shown by cassiterite samples during thermal demagnetization. At about 525°C ($\pm 25^\circ\text{C}$) their magnetic moment dropped sharply to zero; this temperature is close to the curie point of manganoferrite⁴.

To test the stability of magnetization of cassiterite oriented samples were collected from the greisen body 'Huber' in Horní Slavkov (western Czechoslovakia), which contains grains of cassiterite. Their J_n directions shown in Fig. 1 differ markedly from the direction of the present-day geomagnetic field and are similar to the directions of the magnetization found in rocks of Permo-Carboniferous age from that region. Fig. 2 shows a.c. and thermal demagnetization curves for six and five greisen samples, respectively, their J_n directions being included in Fig. 1. The a.c. and thermal demagnetization curves of the greisen samples are similar to those from cassiterite monocystals and

GEOLOGY

Isotopic Ages and Andean Uplift

aggregates. Tables 1 and 2 summarize the data derived from measurements during demagnetization of samples, the demagnetization curves of which are shown in Fig. 2. Laboratory tests show a high palaeomagnetic stability of cassiterite. The J_n directions corresponding to those of other Permo-Carboniferous rocks are in agreement with the generally accepted Permo-Carboniferous age of cassiterite-wolframite formation of western Czechoslovakia, which represents a genetic analogue of the ore mineralization in Cornwall.

The magnetization of cassiterites was described by Ramdohr⁶, who attributed it to an admixture of columbite. The samples of pure columbite which were examined, however, had a much lower remanent magnetization than magnetic samples of cassiterite in which columbite is only a minor component. Microscopic and X-ray analysis did not show the presence of any heterogeneous mineral admixture even in the strongly magnetic samples. On the contrary, the identical properties of cassiterite (in particular, the curie point, the course of a.c. demagnetization, high value of the Q_n -coefficient) shown in samples from various localities point against heterogeneous admixtures of various ferromagnetics as principal bearers of magnetization of cassiterite. The results of quantitative spectral analysis (the constant-temperature arc method) showed that samples with higher magnetization had a generally higher content of iron not exceeding 0.6 per cent. It is assumed that iron is bound in cassiterite to the structural lattice which is in agreement with the finding of Stumpff⁷ based on assays with an electronic microsonde. It is probable that many minerals generally considered as 'non-magnetic' can bind to their structural lattice elements in such a way as to render them naturally ferromagnetic.

We thank Dr. K. Tuček, director of the Mineralogical Department of the National Museum in Prague, for samples of cassiterite and other minerals used in the investigation.

AN outline of the research programme undertaken from University College, London, to elucidate the history of Andean Uplift in northern Chile has recently been presented in *Nature*¹. Locally, in the San Bartolo area, the post-Cretaceous geological history has been fairly clearly established from work carried out in 1961 (ref. 2). The chronology established, however, was entirely relative, in the absence of fossil evidence in this suite of continental sediments and volcanic rocks. Thus the San Bartolo ignimbrite formation, which is part of the Formation Liparítica of Bruggen³, was regarded by him as Miocene or younger. Other workers, however, have suggested chronologies which imply a late Pliocene or Pleistocene age⁴.

Previous age determinations on the ignimbrites by the Branch of Isotope Geology of the U.S. Geological Survey⁵ gave a minimum age of 5 million years and practically eliminated the possibility of a Pleistocene age.

The field work^{2,6} has shown that the deposition of the ignimbrite formation, which consists of a number of flows separated by gravels, bears a close relation to the tectonic activity which warped the early Tertiary planation surface and which produced much of the present Andean relief. In fact, the deformation of the originally planar surfaces of the ignimbrite flows provides much of the evidence of tectonic activity. The latter was episodic; it began shortly before and continued after the period of ignimbrite eruption. The possibility arises, therefore, not only of dating particular events, but also of determining the time span of ignimbrite eruption and therefore of determining the rate of Andean uplift.

The ignimbrites contain large biotite phenocrysts and provide admirable material for isotopic age determination by the potassium-argon method. The ages obtained can be linked with every confidence to the time of consolidation of the flows.

Four specimens were selected for the preliminary investigation, which has been carried out at Cambridge. Two specimens, 868 and 869, come from prominent flows close to the bottom and top of the ignimbrite formation according to the succession established in the San Bartolo area². The Puripicar tuff (869) has a large aerial extent of about 1,000 km² and is supposed to have originated from fissure eruptions now covered by the Plio-Pleistocene volcanics of the high Andes.

* K₂O analyses by A. E. S. Mayer at Univ. Coll., Lond.

The age determinations of these two specimens show that the ignimbrite eruptions date from Upper Miocene⁷ and continued through much of the Pliocene. Some six million years were therefore available for the accompanying tectonic activity. A considerable part of Andean uplift must have been accomplished during this time. Tectonic activity (and less significant ignimbrite eruption) continued after the eruption of the Puripicar tuff, however, and a considerable proportion of Andean uplift must also be late Pliocene or Pleistocene^{2,6}. If the total period of Andean uplift is taken as approximately the ten million years from late Miocene time, the average rate of uplift to the 4,000 m of the Puna surface (which, in fact, was episodic²) is less than 0.5 mm/y. Again, it may be con-

firmly inferred that this part of the Andean region was one of low relief until Late Miocene time. The general history of Andean uplift is therefore probably much more similar to that of other Tertiary mountain chains⁸ than has often been supposed.

Specimen 866 comes from a hill of rhyolite at Copacoya which forms an inlier in the Puripicar tuff. Its similarity in petrographic character to the ignimbrites suggests that it may well be a late-stage viscous extension of the degassed magma from a fissure vent which had previously erupted ignimbrites in the succession below the Puripicar tuff. Its age of 7.53 ± 0.05 m.y. conforms with this inference.

Specimen 867 represents a flow from the Chaxcas volcanic dome which erupted ignimbritic material from a central vent within the main area of ignimbrite deposition. The age relations of these central eruptions to the main ignimbrite flows were not certainly known from the field evidence⁹ but the age determination places at least one flow firmly within the main period of ignimbrite eruption.

The determinations presented here effectively show that the eruption of the Formación Liparítica covered a wide time span. Flows of this formation occur interbedded with continental sediments in the Salar de Atacama and in the basin of the River Loa¹. It is hoped to undertake further work on these flows to provide a radiometric time-scale for the geological history of these regions also.

CHEMISTRY

Nomadic Behaviour of Yttrium Ions and their Structure in Solution

Two basic problems have long been predominant in the solution chemistry of the rare earth elements: the directional change of sequential properties at gadolinium, and the nomadic behaviour of the yttrium ion. Treatment of the 'gadolinium break' appears amenable to the ligand field approach, but the adoption by yttrium of a serial position differing with the nature of the menstruum has not been so classically explained. The inception of ion exchange techniques for separation of the rare earth elements has indeed tended to distract attention from this problem which was ever-present in the older classical methods of separation by fractional crystallization or precipitation.

Nomadism of the yttrium ion in a separating rare earth sequence has, in the past, been attributed to functional covalency or an 'elastic' property of the yttrium ion¹ or even to the possible formation of a 'yttryl' ion². Now, however, the ability of yttrium ions to locate at varying sites in the lanthanon series is found attributable to its participation in hydroxy polymer formation. The structures formed are of the type shown by Salmon and Wall³

and Randall and Staveley⁴ to be formed by aluminium ions, and by Pokras and Kilpatrick⁵ to exist in scandium solutions. Suggestive evidence for such polymer systems in yttrium solutions can be found in the literature and was emphasized in the current work by preliminary studies of solvent extraction and reaction velocities. Final definition has, however, been made by X-ray diffraction studies on yttrium solutions.

The technique employed was virtually that used by Brady *et al.*⁶. Because ions of different scattering power were involved, radial distribution functions were calculated in terms of electron density by the generalized Fourier approach:

$$\Sigma 4\pi r^2 K_m \rho_m(r) = 4\pi r^2 \rho_0 \Sigma Z_m + 2r/\pi \int_0^\infty s i(s) \sin r s ds$$

Warren, Krutter and Morningstar⁷ and, more recently, Brady⁸ have adequately described this procedure.

The formation of polymers based on hydroxyl bonded yttrium ions necessitates the existence of a Y-O association. Analysis of diffraction patterns and radial distribution functions shows clearly that this exists in sulphate and nitrate solutions, and can occur to a minor extent in chloride solutions through the development of Cl-O bonds, but does not occur in perchlorate solutions (Figs. 1-4).

Two types of Y-O bonds are, however, seen: that forming with the associated anion (Y-O)' and that essentially responsible for polymer formation, formed with a hydroxyl bridge (Y-O)". The proportion of (Y-O)' and (Y-O)" bonds in a solution depends on the associated anion and pH. Neither type of association occurs in perchlorate solutions. (Y-O)' type bonds form in chloride solution only at low pH—high acidities appear to degrade (Y-O)"

Fig. 1. Radial distribution in 2 M $Y(ClO_4)_3$ solution

Fig. 2. Radial distribution in 2 M YCl_3 solution

Fig. 3. Radial distribution in 2 M $\text{Y}(\text{NO}_3)_3$ solutionFig. 4. Radial distribution in 1 M $\text{Y}_2(\text{SO}_4)_3$ solution

type bondings. The proportion of $(\text{Y}-\text{O})''$ to $(\text{Y}-\text{O})'$ bonds is greater in sulphate than in nitrate solution, and only species containing $(\text{Y}-\text{O})'$ bonds extract into an organic phase from aqueous solution.

Reaction velocity studies have permitted the rough calculation of activation energies (E_{In}) for associated yttrium ions. These increase generally as:

$\text{Y}(\text{ClO}_4)_3$: 63.5 YCl_3 : 74.3 $\text{Y}(\text{NO}_3)_3$: 88.7 $\text{Y}_2(\text{SO}_4)_3$: 92.6 and we may relate the differing values of E_{In} to the degree of hydroxy-polymer formation by taking the hydroxyl bridge bonding energy as ~ 5 kcal (ref. 8).

This, together with modular analysis, shows that in chloride solution, the polymer is, at the most, dimeric; in nitrate solutions it is probable that quadri- or sexa-polymers are formed, with a penta-polymer representing the average situation. The polymers formed in sulphate solution appear to hold six bridging groups.

In contrast, Brady⁶ has shown that erbium solutions are completely ordered, with no evidence indicated for the formation of polymers. Solvent extraction and reaction velocity studies have provided additional confirmation of the non-existence of aquo-polymeric cations of the other lanthanons although lanthanum itself appears to exhibit a very slight tendency to polymer formation under specific conditions.

Degradation of the yttrium hydroxy polymers is found to depend on the polarizing effect of an added reactant. This effect appears to relate not only to the total ionic charge developed on dissociation of the reactant molecule, but also to a summation of the ionic susceptibilities of the added ions:

$$P = Z_e \sum_{\text{zan}}^{\text{cat}}$$

A close relationship has been found between P and reaction velocities.

We can consider then the position of yttrium in a lanthanon series in terms of polymer formation in which yttrium ions, as hydroxyl-bridged moieties, possess co-ordination numbers greater than 6 (that of the lighter lanthanons). The sequential separation location of yttrium is then determined by the degradation of these polymers of effective C.N. 12 to C.N. 9 (dimers) or C.N. 6 (monomers) according to the polarization factor of the reactant system. Where little or no degradation takes place, yttrium will be located close to lanthanum (as in the double ferricyanide precipitation); where breakdown to dimers is effected, yttrium will be positioned in the neodymium-terbium region (as in hydroxide, nitrate, cobalticyanide or simple ferricyanide fractionations); where complete monomerization obtains, yttrium will adopt its 'normal' ionic radius position near holmium (ion exchanger, double sulphate, bromate separations).

In addition to presenting a rationale for the nomadic behaviour of yttrium ions, this identification of yttrium hydroxy-polymers has broader implications. As well as in scandium and aluminium solutions (*vide supra*), hydroxyl bridged polymers have been observed in indium solutions by Irving, Rossoti and Williams⁹. Although no studies appear to have been reported on the structures of gallium or thallium solutions, Magnusson¹⁰, in assessing the short-range interactions of aqueous ions on a thermodynamic basis, shows a generic association (in terms of hydration-free energy) of Al^{3+} , Sc^{3+} , and Y^{3+} with Ga^{3+} , In^{3+} and Tl^{3+} rather than with the trivalent lanthanons.

It may be strongly suggested then that polymer formation in aqueous solution is an attribute of Group III elements other than the lanthanons. Whether the $4f$ shell electron complement contributes to this effect presents an interesting area for the ligand field approach.

This note summarizes for the immediate benefit of scientists in this field the results of a broad research programme which has recently been completed. A series of individual papers is in preparation which will present in greater detail experimental data obtained for each phase of the work.

Use of Infra-red Spectroscopy to determine the Orientation of Pyridine sorbed on Montmorillonite

ORGANIC molecules sorbed on layer silicates generally adopt one single orientation. For those molecules for which the assignment of the absorption bands to the different vibrational modes has been well established, this association presents a favourable case for analysis by infra-red spectroscopy. The orientation of the molecules can be inferred from the observed dichroism of specific absorption bands.

This communication reports an analysis of the orientation of pyridine sorbed on montmorillonite. The use of polycrystalline aggregates, in which the orientation is not perfect, restricts the information to a qualitative nature. However, this information is of great use, especially when combined with the results obtained by other techniques.

Fig. 1. Symmetry elements of the pyridine molecule, point group C_{2v} .

Pyridine belongs to the point group C_{2v} (Fig. 1), for which the principal axes and the directions of the changes of the dipole moment coincide. The infra-red-active vibrations are classified, according to their symmetry, in the following classes:

- (1) Symmetry class A_1 , that give dipole moment changes parallel to the z axis (C_2 axis).
- (2) Symmetry class B_1 , that give dipole moment changes parallel to the x axis.
- (3) Symmetry class B_2 , that give dipole moment changes parallel to the y axis.

A_1 and B_1 are in-plane vibrations, while B_2 are out-of-plane vibrations.

The infra-red spectrum of pyridine has been extensively studied and the assignment of most of the observed bands is well established^{1,2}. Some of these bands appear in regions that are well resolved from the silicate absorptions, permitting their separate observation in the spectrum of the silicate-pyridine complex.

According to Greene-Kelly³, pyridine, and several related molecules, adopt two kinds of orientation depending on the surface concentration: for high surface concentrations the plane of the ring is perpendicular to that of the silicate sheet, while at lower surface concentrations the planes of the molecules are parallel to that of the silicate sheet.

Both kinds of complexes have been prepared, the first one by sorbing neutral pyridine molecules on Na-montmorillonite, and the second by introducing the pyridine as a cation. The films of each complex were prepared such that silicate layers were in strongly preferred orientation in the plane of the film.

Pyridine sorbed on Na-montmorillonite exhibits absorptions at 703, 748, 1,217, 1,443, 1,492, 1,596 cm^{-1} and others around 3,000 cm^{-1} . These absorptions are only slightly modified with respect to those of liquid pyridine. We have selected for observation those the assignation of which is unequivocal and are in regions free of silicate absorptions.

Fig. 2 illustrates these absorption bands for two different inclinations of the film. Only the 1,443- cm^{-1} band (class B_1 , dipole moment change parallel to the x -axis) shows significant increase with the incidence angle. The

ratios are: 1.04 (703 cm^{-1} band), 1.04 (748 cm^{-1} band), 1.60 (1,443 cm^{-1} band), and 1.08 (1,492 cm^{-1} band). These results indicate that the molecules are disposed with their planes perpendicular to the silicate layers and with the principal axis (C_2 axis) parallel to the layers.

The infra-red absorption spectrum of the pyridinium ion, which also belongs to the point group C_{2v} , is somewhat modified from that of the sorbed pyridine. Bands have been observed at 677, 748, 1,340, 1,492, 1,550, 1,625, 1,640 cm^{-1} and several others above 3,000 cm^{-1} , in the pyridinium-montmorillonite complex. The position of the bands coincides with those reported previously for the pyridinium ion by other authors⁴⁻⁶.

Although the assignment of the bands for the pyridinium ion is not so well established, it is logical to assign the 677 and 748 cm^{-1} bands to out-of-plane vibrations and those between 1,300 and 1,700 cm^{-1} to in-plane vibrations or combination modes. The 1,492 cm^{-1} band which is present at the same frequency as in pyridine must have the same origin.

In Fig. 3 are represented the absorption bands of the pyridinium ion adsorbed in montmorillonite for two inclinations of the film. Only the 677 and 748 cm^{-1} bands (out-of-plane vibrations, class B_2) with dipole moment changes perpendicular to the molecule plane show significant increase in intensity with the angle of incidence. The

$$\frac{\log \left(\frac{I_0}{I} \right)_{40^\circ}}{\log \left(\frac{I_0}{I} \right)_0}$$

ratios are: 1.80 (677 cm^{-1} band), 1.68 (748 cm^{-1} band), 1.00 (1,492 cm^{-1} band), and 1.01 (1,550 cm^{-1} band). This indicates that the molecules are oriented with their planes parallel to the silicate sheets.

The orientations arrived at by infra-red spectroscopy agree with those inferred by Greene-Kelly from X-ray spacing measurement and one-dimensional Fourier syntheses⁷. They also confirm Greene-Kelly's analysis of the change of birefringence in preferred pyridine-montmorillonite complexes⁷. Our Na-montmorillonite-pyridine gives a spacing of 14.8 Å (8 orders observed) while the montmorillonite-pyridinium gave a spacing of 12.5 Å (6 orders observed).

It is interesting to note the utility of infra-red dichroism measurements of molecules sorbed on layer silicates in determining the symmetry species of the vibrations

Relaxation Effects in the Electrophoresis of Disperse Systems

It was shown by Henry¹ that the movement of spherical particles in an electric field depends on the size of the particle and the ionic strength and that the relationship between mobility and zeta-potential depends on the radius of the particle, a , and the Debye-Hückel double layer thickness, $1/\kappa$. It was pointed out by Overbeek² that, in addition, the relaxation of the ionic atmosphere of the particle must be considered. Overbeek² and Booth³ treated this problem theoretically and obtained analytical expressions for the mobility, which included corrections for retardation and relaxation, in terms of an incomplete power series in zeta-potential the coefficients of which were functions of κa . The limitation of the equations of Overbeek and Booth was that the expressions were only valid for zeta-potentials less than 25 mV. More recently Wiersema⁴ has obtained a numerical solution of the problem which gives mobility as a complete power series in zeta-potential and is valid for potentials greater than 25 mV.

Experimentally, however, little evidence has been accumulated which substantiates the occurrence of relaxation effects in electrophoresis. von Stackelberg *et al.*⁵ examined the mobility of some emulsion droplets in the κa range 10–2,000 and obtained qualitative evidence for relaxation. An indirect observation has also been made by Overbeek⁶ with reference to work carried out by Troelstra and Kruyt⁷ on the electrophoresis of silver iodide

particles in bariura nitrate solutions. No systematic observations appear to have been made using well-characterized, monodisperse solid particles, covering a range of particle diameters and electrolyte concentrations. This communication presents a preliminary report of a detailed examination of the variation of electrophoretic mobility as a function of particle size and electrolyte concentration with such a system.

Using an emulsion polymerization technique, with hydrogen peroxide as the initiator, a series of monodisperse polystyrene latex particles have been prepared with diameters ranging from 600 to 4230 Å. The details are recorded in Table 1. The initial styrene-water emulsion was stabilized by sodium laurate. The latter was later removed by dialysis leaving polystyrene particles with carboxyl surfaces. A mobility against pH curve for latex D, obtained after exhaustive dialysis, is given in Fig. 1. This curve indicates that the surface groupings have a pK of about 4.4. The presence of carboxyl groups has also been confirmed by infra-red spectroscopic studies on the latices.

Table 1

Latex	Diameter in Å
A	600 ± 96
B	1030 ± 82
C	2425 ± 130
D	3680 ± 170
E	4230 ± 160

From the computations of Wiersema⁴ it can be shown that the electrophoretic mobility as a function of κa , at constant electrokinetic potential, gives curves of the form shown in Fig. 2 for 1:1 electrolytes. Thus particles with the same zeta-potential, but different radii, can have different mobilities according to the κa region in which they fall. The mobilities of the latex particles of different sizes were determined in sodium chloride solutions, of constant ionic strength, at pH 7.5. The results at sodium chloride concentrations of 5×10^{-5} M, 10^{-2} M and 5×10^{-2} M are plotted against $\log \kappa a$ in Fig. 2. At a salt concentration of 5×10^{-5} M the results for latices A, B and C fall on the theoretical curve which corresponds to a zeta-potential of 59 mV. A minimum occurs in the mobility values at a κa value close to 2, in agreement with the position of the minimum on the curves derived from Wiersema's computations.

At a salt concentration of 10^{-2} M, with latices A, B and C, the minimum disappears and the results lie on an ascending curve. A further increase of electrolyte concentration to 5×10^{-2} M shifts the curve to higher κa values and decreases the slope of the curve. At both salt concentrations the correspondence of the experimental results with the theoretical curves is good. Latices D and E clearly have higher surface potentials than A, B and C, but the shift produced by changing the salt

Fig. 1. Electrophoretic mobility against pH for latex D after exhaustive dialysis in 5×10^{-4} M sodium chloride solution

Fig. 2. Mobility against κa . Theoretical curves for zeta-potentials of 50 mV, —; 32 mV, ----; and 20 mV, Results obtained in sodium chloride solutions: ○, 5×10^{-3} M; Δ, 10^{-3} M; □, 5×10^{-3} M. Latices, A, ○; B, Δ; C, □; D, +; E, -.

concentration is consistent with that expected on the basis of relaxation. The pattern of the results obtained in sodium chloride solutions has also been confirmed with 2:1 and 3:1 electrolytes.

The minimum in the mobility results for latices A, B and C in 5×10^{-3} M salt solution and the behaviour of the mobility against κa curves with increasing ionic strength are all indications that relaxation is a real effect in the electrophoresis of colloidal particles. The results obtained, moreover, appear to agree quite closely with the behaviour predicted by Wiersema⁴. Comparison of mobilities, as a function of κa , at constant zeta-potential and ionic strength can be made from the experimental data obtained, but this would not constitute an independent test of the theory unless the zeta-potential was measured by a completely independent method.

A more detailed account of the electrophoretic properties of the latices as well as studies on their stability and viscous properties will appear in due course.

We would like to thank I.C.I., Ltd., Blackley, for financial support of this work, and Prof. J. Th. G. Overbeek and Dr. P. H. Wiersema for a number of discussions on the relaxation effect.

Ultra-violet Absorption Spectra of Aromatic Nitrenes and Dinitrenes

NITRENES, molecular fragments with an electron sextet on nitrogen, are known to be the primary products of the decomposition of organic azides¹⁻³. Their existence as separate intermediates and their triplet character were recently demonstrated by electron spin resonance spectroscopy⁴. We have investigated the photolysis of several aromatic azides and diazides in organic glasses at 77° K in an attempt to trap the nitrenes presumably formed. Three types of behaviour were observed.

Fig. 1. Absorption spectra of nitrenes. a, b, c refer to the azides, the nitrenes, and the final products after melting, respectively: I, phenyl azide; II, α -naphthyl azide; III, 4,4'-diazidobiphenyl.

Phenyl azide and its derivatives gave, on irradiation with ultra-violet light, intermediates in sufficient concentration for their absorption spectra to be observed. In Fig. 1, Ib, the long wave-length bands of phenyl nitrene are clearly visible and are, incidentally, very similar to the corresponding absorption bands of the benzyl radical⁵. The nitrene is, however, destroyed by prolonged irradiation and only partial conversion of the azide to the nitrene is achieved. With α -naphthyl azide (Fig. 1, II) and the diazides of more extended conjugated systems (for example, 4,4'-diazidobiphenyl in Fig. 1, III) high conversion yields or complete conversion were obtained.

Molecules where the azido group is attached to a heterocyclic ring with two heteroatoms did not give detectable intermediates.

o-Azidobiphenyl is a special case; at 77° K in the solid matrix the azide is changed directly into the final stable product, carbazole.

Where detectable intermediates were formed they were stable in the organic glass at liquid nitrogen temperature, but disappeared on melting or on slightly softening the glass. The absorption of the intermediates was independent of the solvent used; spectra taken in glasses of methylcyclohexane, 3-methylpentane, and EPA, a mixture of diethyl ether, isopentane and ethyl alcohol 5:5:2, were identical. The intermediates react with oxygen even at

77° K with the formation of a transient which absorbs in the visible and disappears on melting. It is felt that these results, together with the bulk of the chemical evidence, justify the assignment of the observed spectra to nitrenes.

BIOCHEMISTRY

Transphosphorylation of Adenosine Di- and Tri-phosphates in the Presence of Calcium Phosphate Precipitates

It has been discovered by Lowenstein^{1,2} that in dilute aqueous solution in the presence of certain divalent cations there is a tendency for the terminal phosphate group of the adenosine triphosphate ion (ATP) to be transferred to inorganic phosphate or other suitable acceptor. For example:

where ADP represents the adenosine diphosphate ion. Krane and Glimcher³ have recently shown that a similar non-enzymatic transphosphorylation occurs on the surface of calcium phosphate crystals with hydroxyapatite structure when they are in contact with aqueous solutions of ATP. In this reaction the acceptor is phosphate belonging to the crystal. The rate of reaction is faster and less dependent on pH than that of Lowenstein.

It has now been found, during experiments on the interactions of calcium, phosphate, and certain polyphosphate ions in aqueous solution (to be reported in detail later), that a mixture containing freshly precipitated, apparently amorphous, calcium phosphate is an efficient transphosphorylating medium for ATP and also ADP; especially if the nucleotide is initially in acid solution and is then co-precipitated by adding alkali. The pH dependence of transphosphorylation resembles that of Krane and Glimcher³, but the rate is slower. In a typical experiment a mixture containing trisodium phosphate (0.04 M), calcium chloride (0.07 M), and the sodium salt of ADP (0.02 M) was acidified to pH 4 with hydrochloric acid. Sodium hydroxide (1.0 N) was then added to pH 7.7 and the mixture made up to standard volume to give the concentrations in brackets. The precipitate contained initially 75 per cent of the ADP, 75 per cent of the phosphate, and 93 per cent of the calcium. The whole mixture was incubated at 38° C and at intervals portions were analysed chromatographically^{1,4}. Fig. 1, in which the ordinates give molar percentages referred to the initial ADP concentration, shows that during incubation the ADP concentration (Curve 1) decreased. At the same time an almost equivalent amount of adenosine monophosphate (AMP) (Curve 2) and a smaller amount of pyrophosphate (Curve 3) were formed. There was a much smaller decrease in ADP concentration in a control mixture containing no phosphate (Curve 4). No pyrophosphate was formed, although a small amount of AMP was formed, probably by hydrolysis of ADP. Very little pyrophosphate was formed in another control mixture containing no ADP.

The effect of the incubation of ATP in place of ADP under the foregoing conditions is shown in Fig. 2. Initially, the precipitate contained 59 per cent of the ATP, 74 per cent of the phosphate, and 93 per cent of the calcium. The ATP concentration (Curve 1) decreased rapidly and ADP

(Curve 2) and pyrophosphate (Curve 3) were formed. AMP (Curve 4) was also formed, although more slowly, presumably from ADP as in Fig. 1. The ATP concentration in a control mixture containing no phosphate decreased appreciably (Curve 5), probably by hydrolysis in the presence of calcium ions⁵, although there was little formation of pyrophosphate or AMP.

These results were reproducible and were unaffected by addition of chloroform or thymol to prevent biological growth. It is therefore concluded that non-enzymatic transphosphorylation from ADP and ATP to phosphate occurred in the presence of the calcium phosphate precipitates. Transphosphorylation appeared to be more closely associated with the precipitates than with the solution. Thus incubation of supernatant solutions after centrifuging off the precipitate yielded much less pyrophosphate than would have been expected if transphosphorylation occurred only in solution. Other experiments with ATP in which different conditions of precipitation were used showed that the extent of pyrophosphate formation increased as the proportion of ATP in the precipitate increased. Pyrophosphate formation was 30 per cent lower after 48 h when ATP was added to freshly precipitated calcium phosphate instead of being co-precipitated. At ATP concentrations less than 0.005 M, all the ATP precipitated and the initial rate of pyrophosphate formation (0.03 mole/mole of precipitated phosphate/h at 38°) was almost independent of ATP concentration—as might be expected for heterogeneous reaction.

It therefore appears that the environment provided by freshly precipitated slightly alkaline calcium phosphate is

Fig. 1

Fig. 2

favourable for non-enzymatic transphosphorylations. Preliminary electron diffraction and X-ray diffraction measurements showed that the precipitates were amorphous and did not change on incubation.

I thank Dr. G. H. Taylor, Dr. H. J. Kisch, and Dr. J. Donderdale of the C.S.I.R.O. Division of Coal Research for diffraction measurements and interpretations; and Mr. R. F. Sloggett for assistance with analyses.

An *in vitro* Action of Human Growth Hormone in the Presence of Actinomycin D

THE *in vitro* addition of growth hormone to isolated diaphragm from the hypophysectomized rat stimulates the uptake of glucose¹⁻³, the incorporation into protein of natural amino-acids³⁻⁵ and the accumulation in the tissue in an unchanged state of certain natural and unnatural amino-acids^{6,7}. These effects are similar to those of insulin on isolated diaphragm from the normal or the hypophysectomized rat⁸. Eboue-Bonis *et al.*⁹ have recently found that the action of insulin *in vitro* in promoting glucose uptake and the incorporation into protein of label from labelled natural amino-acids is still seen in the presence of actinomycin D—a powerful inhibitor of the synthesis of nucleic acid¹⁰. We have investigated the influence of actinomycin D on the effectiveness of human growth hormone in promoting the incorporation into protein of ¹⁴C from glycine-¹⁴C-U and into nucleic acid of ¹⁴C from orotic acid 6-¹⁴C, when the hormone is added *in vitro* to isolated diaphragm from hypophysectomized rats.

The general methods were those of Manchester and Young³ except that glucose was estimated by a glucose oxidase method¹¹ and the amounts of radioactive carbon incorporated into protein and into nucleic acid were estimated by a method involving a combination of those used by Manchester¹² and Wool¹³. For this, material derived from a hemidiaphragm, which had been incubated with labelled glycine and labelled orotic acid simultaneously, was used. Preliminary experiments showed that under the conditions used the labelling of protein from labelled orotic acid was less than 10 per cent of that from labelled glycine, and that the labelling of nucleic acid from labelled glycine was less than 10 per cent of that from labelled orotic acid. Because the labelling of nucleic acid, though not of protein, was diminished when glucose was present in the medium, glucose was omitted from the medium in those experiments which were not concerned with a determination of the uptake of glucose by the isolated diaphragm. Actinomycin D was added to the medium in some experiments at a concentration of 10 µg/ml. of medium, the diaphragm being soaked in buffer containing this concentration of actinomycin before transfer to the incubation flask.

Paired hemidiaphragms were incubated in the presence of 1 mM glycine-¹⁴C-U (0.1 µc./ml.) and 0.01 mM orotic acid 6-¹⁴C (0.1 µc./ml.), and after 2 h were homogenized in 5 ml. of 10 per cent trichloroacetic acid at 0° C. The insoluble material was washed repeatedly with trichloroacetic acid at 0° C and fat-soluble material removed by extraction with 96 per cent ethanol at 0° C. Nucleic acid was then extracted into 10 per cent aqueous sodium chloride at 100° C and the sodium nucleates estimated by the method of Wool¹³. Protein was extracted from the

Fig. 1. The *in vitro* effect of human growth hormone and actinomycin D on the incorporation of glycine-¹⁴C and orotic acid-¹⁴C into protein and nucleic acid respectively. In experiments B and D growth hormone at 50 µg/ml. was present *in vitro* while in F and H the concentration was 10 µg/ml. In experiments C, D, G and H actinomycin D was present in a concentration of 10 µg/ml. The results illustrated represent the mean results for four groups of paired hemidiaphragms. The vertical lines at the top of the columns represent the standard errors of the mean value.

sodium chloride-insoluble material into 0.4 N sodium hydroxide, and precipitated by 7 per cent perchloric acid which was then heated to 95° C for 20 min. The protein was then estimated by the method of Manchester¹².

As was to be expected³, growth hormone did not promote the uptake of glucose, or the incorporation into protein of label from glycine when the hormone was added *in vitro* to diaphragm from normal rats, but did so with diaphragm from hypophysectomized rats. These results are not illustrated. The observations illustrated in Fig. 1 show that the addition of human growth hormone to the medium in a concentration of 50 µg/ml. or 10 µg/ml. increased the incorporation into protein of label from glycine to a statistically significant extent, whether or not actinomycin was present in the medium. On the other hand, in the presence of actinomycin the incorporation into nucleic acid of the label from orotic acid was reduced to 5–10 per cent of that in its absence. Under the conditions of these experiments no evidence was seen of a significant change in the rate of nucleic acid synthesis when growth hormone was added *in vitro*.

Wool^{13,14} suggested that insulin may exert a primary action on the synthesis of ribonucleic acid, the latter acting as 'messenger RNA'¹⁵ with respect to the promotion of protein biosynthesis under the influence of this hormone. The evidence provided by Eboue-Bonis *et al.*⁹ did not support this idea. The results recorded here likewise do not agree with any idea that growth hormone promotes protein biosynthesis by way of a primary action on the production of messenger RNA. Since, under the conditions of our experiments, actinomycin did not completely suppress the incorporation of label from orotic acid into nucleic acid, though much of this residual incorporation may be the terminal labelling of 'transfer RNA'¹⁶, no firm statement can be made that growth hormone continued to promote protein biosynthesis when all RNA synthesis had been abolished.

We have sought, but failed, to find evidence that growth hormone stimulates protein biosynthesis by a primary action on the production of messenger RNA.

The results of these investigations are represented in Fig. 1. The growth hormone preparation showed a statistically significant stimulation of amino-acid incorporation at both 50 µg/ml. and 10 µg/ml., and it is seen

that the stimulation is unaffected by actinomycin, which has reduced the incorporation of orotic acid into nucleic acid to 5–10 per cent of the control values. The results presented here do not enable us to report any effect of growth hormone on nucleic acid synthesis, although experiments designed to study this more closely may reveal such effects.

During the writing of this communication Goodman¹⁶ reported that Knobil has also evidence that the action of growth hormone in stimulating protein biosynthesis still occurs when the production of new nucleic acid in the muscle cell is inhibited.

We thank Dr. A. Stockell Hartree for purified human growth hormone, Miss M. B. Thomas for the hypophysectomies and Mr. D. C. Gardiner for general assistance.

Long-spacing Segments from Renatured $\alpha 1$ Sub-units of Collagen

THE mammalian collagen molecule is thought to be composed of two $\alpha 1$ and one $\alpha 2$ peptide chains. Alpha 1 and $\alpha 2$ have approximately the same molecular weight but differ in their amino-acid composition¹. A mixture of $\alpha 1$ and $\alpha 2$ in the ratio of 2:1 (produced by the denaturation of neutral salt-soluble rat skin collagen) re-forms, under certain conditions suitable for renaturation, as much as 50 per cent of the rod-like collagen molecules². It is of interest to learn whether the triple helix of the collagen molecule can also be formed from three $\alpha 1$ chains. Recently, Piez and Carrillo³ have investigated the renaturation of the isolated sub-units ($\alpha 1$, $\alpha 2$, and β_{12}) of collagen at 15°. According to our experience these conditions are not optimal for the formation of the triple helix⁴.

We isolated the $\alpha 1$ component from neutral salt-soluble calf skin collagen according to the method of Piez *et al.*¹. Its homogeneity was checked by means of ultracentrifugation and starch-gel electrophoresis. Renaturation was achieved by incubating at a collagen concentration of 2.6 mg/ml. for 100 h at 22° in 0.25 M sodium citrate buffer, pH 3.7. The denaturation curve of the renatured solution gave a value of 30° for T_m (defined according to v. Hippel *et al.*⁵). Renatured acid-soluble collagen from calf skin has a T_m of 33° after renaturation under identical conditions.

When examined in the ultracentrifuge the renatured material showed, in addition to $\alpha 1$, a second, slower sedimenting peak which, during the course of the renaturation, grew at the expense of the $\alpha 1$ peak. Following the addition of pepsin (weight ratio of collagen: enzyme of 10:1; temp., 25°) the $\alpha 1$ component disappeared while the slower, pepsin-resistant peak, although not quite so sharp as the native molecule (Fig. 1), sedimented at approximately the same rate.

It was possible to produce long-spacing segments (Fig. 2) from the pepsin-resistant material, which accounted for

Fig. 1. Sedimentation diagram of renatured $\alpha 1$ after 18-h pepsin treatment; concentration prior to pepsin addition 2.6 mg collagen/ml. in 0.25 M citrate buffer, pH 3.7; temp., 22°; 59,000 r.p.m.; phase angle, 66°; photographed after 150 min.

Fig. 2. Long-spacing segments from renatured $\alpha 1$ sub-units, produced by dialysis of the pepsin-treated solution in 0.05 per cent acetic acid against 0.4 per cent ATP solution, pH 3.5; stained with phosphotungstic acid and counterstained with uranylacetate.

almost 40 per cent of the starting material. The cross-striation pattern appeared to be the same with respect to the position of the individual cross-striations when compared with normal collagen. There appears to be some difference in the intensities of the individual bands. An exact photometric evaluation of the cross-striation pattern remains to be done.

These preliminary experiments indicate that it is possible to build a native-like triple helix from three $\alpha 1$ chains. The cross-striation pattern of the segments thus obtained from $\alpha 1$ argues against the collagen model of Hodge⁶ in which the $\alpha 1$ chain would be built up from five identical sub-sub-units and the $\alpha 2$ chain from seven identical sub-sub-units. If this were the case, then the cross-striation pattern of the long-spacing segments formed from $\alpha 1$ should be divided into five equal periods. The fact that no repeating period at all is evident suggests that it is very unlikely that $\alpha 1$ is composed of several identical smaller sub-units.

This investigation was supported by the Deutsche Forschungsgemeinschaft.

Glycogen in Yeast Form of *Paracoccidioides brasiliensis*

Paracoccidioides brasiliensis is the causative agent of South American blastomycosis. McKinnon and Vinelli¹, and Carbonell *et al.*², suggested in their histochemical investigations that the yeast form of this fungus may contain glycogen. The present investigation deals with the biochemical identification of glycogen in the yeast form of *P. brasiliensis*. The fungus used (strain No. 8159 of the Instituto Nacional de Tuberculosis, Caracas, Venezuela) was originally isolated from a lymph node in a human systemic infection and cultured on brain heart infusion agar (Baltimore Biological Laboratory) with human blood (10 per cent) and antibiotics (penicillin, 20 units per ml.; streptomycin, 400 µg per ml.) at 37° C. The fungus was collected on the fifth day of culture, and washed 4 times with distilled water by centrifugation (500 g, 5 min). After extracting the lipids by means of a mixture of ethanol and ether (3:1), the fungus, suspended in distilled water, was disintegrated in a Branson sonifier at 20 kc/s for 20 min. The disruption of the cell material was completed by treatment in a Waring blender for 1 h. The polysaccharide was isolated according to the method of Abdel-Akher and Smith³, that is, extraction with boiling water, removal of proteins by trichloroacetic acid, and purification by repeated precipitation from aqueous solution with ethanol. From 7.04 g of vacuum-dried fungus material, a polysaccharide fraction (126 mg), acetone-soluble lipids (977 mg) and acetone-insoluble lipids (110 mg) were obtained.

The isolated polysaccharides dissolved easily in water, showing opalescence. A reddish brown colour was produced with iodine. After hydrolysis in N HCl for 3 h in a boiling-water bath, 64 per cent of the weight was liberated as glucose which was determined enzymatically by the combined system of hexokinase and glucose-6-phosphate dehydrogenase⁴. This value was almost equal to that of 65 per cent obtained after the digestion by 'Diazyme' (Miles Chemical Company). 'Diazyme' contains amylase and amyloglucosidase and is used in quantitative determinations of glycogen⁵. After complete hydrolysis by phosphorylase and amyloglucosidase, the ratio of glucose-1-phosphate to glucose was determined to be 10:9 according to the method of Bueding and Hawkins⁶. This result implies that the polyglucose contained in the fungus represents glycogen and not starch.

The polysaccharide fraction contained, besides glycogen, other compounds which were demonstrated by chemical analysis. The total sugar content of the dry material, evaluated by the anthrone method⁷ with glucose as standard, was found to be 85 per cent. The material contained 1.7 per cent nitrogen⁸, 3.2 per cent proteins⁹ with bovine serum albumin as standard, 0.4 per cent total phosphorus¹⁰, less than 1.2 per cent glucosamine¹¹, and less than 2.0 per cent pentoses¹² with xylose as standard. Ketosugars¹³ and uronic acids¹⁴ could not be detected.

The results reported here suggested that most of the nitrogen was not derived from glucosamine but probably from proteins. In order to remove the proteins, part of the polysaccharide fraction was treated with 30 per cent potassium hydroxide for 2 h in a boiling-water bath and purified by repeated precipitation (3 times) from aqueous solution with ethanol. This alkali-treated polysaccharide fraction contained as much as 80 per cent glycogen, as found after acid hydrolysis or digestion by 'Diazyme' or phosphorylase. The ratio of glucose-1-phosphate to glucose was 10:5. This alkali-treated polysaccharide fraction contained the following substances: sugars (as glucose), 95 per cent; nitrogen, less than 0.2 per cent; proteins, less than 0.5 per cent; pentoses, less than 0.5 per cent.

The difference between the glucose content as found by specific enzymatic methods and the total sugar content as obtained by the anthrone method is apparently due to the presence of other sugars. After hydrolysis in N sulphuric

Fig. 1. Glycogen content and growth of *Paracoccidioides brasiliensis* cultured on blood agar

acid for 4 h in a boiling-water bath and after neutralization with barium carbonate, mannose was found by paper chromatography, using various solvent systems; phenol¹⁵, *s*-collidine¹⁵, and ethyl acetate-water-acetic acid (3:3:1)¹⁶. Mannose may exist in the polysaccharide fraction as mannan in combination with glycogen.

The relationship between glycogen content and age of culture was studied as follows: the fungus, collected after various periods of culture, was washed 4 times with distilled water and, after extraction of lipids, the glycogen-containing fractions were prepared by the method described here. To remove glucose and glucose-6-phosphate, the concentrated fractions were dialysed against cold distilled water for 24 h instead of treating them with trichloroacetic acid and ethanol. The fractions containing less than 2 mg of polysaccharides were digested with 2 mg of 'Diazyme' at 40° C for 2 h in a total volume of 5 ml. of acetate buffer (0.02 M, pH 5.0). After digestion, the liberated glucose was determined enzymatically. As shown in Fig. 1, the glycogen synthesized during the lag and logarithmic growth phases is consumed rapidly after the onset of the stationary phase. This finding is in agreement with earlier histochemical results².

We thank Dr. K. Gaede for his advice and Mr. J. Rodriguez for his assistance in the culture of the fungus.

PHYSIOLOGY

Plasma Growth-hormone Levels in Chronic Starvation in Man

BOTH fasting and induced hypoglycaemia are powerful stimuli to secretion of growth hormone in man¹⁻³, but the effect of prolonged starvation on secretion of growth

Fig. 1. Concentrations of growth hormone, cortisol and glucose before and during an intravenous insulin-tolerance test in two young female subjects with chronic starvation due to anorexia nervosa. Case 1 shown by continuous lines; Case 2 by interrupted lines. The test in Case 2 was terminated with glucose at 60 min because of severe neuroglycopenic symptoms. ○, Cortisol, μg/100 ml; *, glucose, mg/100 ml; ■, growth hormone, μmg/ml.

hormone is unknown. It has been suggested, on indirect evidence⁴, that secretion of growth hormone is impaired in chronic malnutrition.

We have measured levels of growth hormone in plasma by a sensitive and specific radioimmunoassay technique⁵ in two young female subjects with profound chronic under-nutrition due to primary anorexia nervosa before and during insulin-induced hypoglycaemia. Each subject was a typical example of the condition, had recently lost two stone or more in weight and, at the time of examination, weighed less than 70 lb. Total daily dietary intake was unknown but estimated to be less than 400 calories. Since food and even minimal exercise may profoundly alter the level of growth hormone in the blood², assays were carried out with the subjects in bed after an overnight fast and during the course of a standard intravenous insulin-tolerance test (0.1 U/kg body-weight). Glucose was measured by glucose oxidase, cortisol by fluorimetry.

The results, shown in Fig. 1, indicate high levels of growth hormone in the plasma at rest (upper limit of normal less than 10 μmg/ml.) with no response in one subject, and a minimal non-sustained increase in the other in response to an induced hypoglycaemic stimulus adequate to produce neuroglycopenic symptoms. Plasma cortisol responses were similar; fasting-levels were high (upper limit of normal, less than 25 μg/100 ml.) and increased minimally, or not at all, during induced hypoglycaemia.

The suggestion is made that the stimulus to growth hormone produced by starvation is, or is near, maximal and the high level achieved thereby is responsible for prevention of death from fasting hypoglycaemia, but, because of limited reserve capacity, resistance to induced hypoglycaemia is reduced⁶.

Fasting Levels of Growth Hormone in Men and Women

THE finding of a twenty-fold difference in fasting sera between adult females and males, as reported by Unger *et al.*¹, is intriguing. It may serve to explain the higher free fatty acid levels observed in both healthy and diabetic female subjects compared with males², for the effect of growth hormone both *in vitro* and *in vivo* on enhancing the lipolytic activity of adipose tissue is well known³. On the other hand, the possibility that at least part of this sex-difference may be attributed to the presence of prolactin must be considered. This might occur in either or both of the following ways: (1) the growth hormone antigen used contained some contaminating prolactin; (2) human prolactin cross-reacts with anti-human growth hormone antisera. The biochemical similarity between these two polypeptides is well known⁴ and the *in vivo* similarity between them has also been noted⁵. The problem of immunological specificity is also open to some question, as recently discussed by Berson *et al.*⁶. Indeed, Hayashida⁷ has considered the evidence that human prolactin and growth hormone represent different activities of the same molecule. Greenwood⁸ has also reported that he has noted a cross-reacting substance in plasma throughout pregnancy, and also in placental extracts. This presumably is related to the placental lactogen of Josimovich, which has been shown to be immunologically similar to growth hormone⁹.

In conclusion, it appears that no definite statement can be made at the present time regarding the significance of this sex difference in serum growth-hormone-levels. The possibilities are either that this has a true physiological significance or that the higher levels in females simply represent cross-reacting prolactin. Some of this controversy may be resolved by comparing the levels of growth hormone in the pre-pubertal age group.

Antidiuretic Hormone and Bile Flow

DURING experiments related to the excretion of manganese¹, variations in flow of bile in the rat suggested the possibility that bile flow is sensitive to the action of the antidiuretic hormone.

Intravenous injections of 'Pitressin' (Parke-Davis 0.3-0.6 pressor units/100 g) into rats induced a sudden short-lived diminution of bile flow. In this investigation the bile was delivered directly on to filter-paper strips via polyethylene catheters and the diameter of the round spots was measured with callipers to the nearest 0.1 mm. The standard curve shown in Fig. 1 relates this measurement to the volume of bile. Collections lasted between 10 and 150 sec, producing spots between 11 and 21 mm in diameter.

The sharp fall of the bile flow after pitressin is shown on Fig. 2. This fall had a mean and standard deviation of 70 ± 10 per cent in the seventeen animals tested. The basal level oscillated around a fairly constant mean, even if the experiments lasted for 3 h. These oscillations were present regardless of the animals' state of hydration.

The pattern shown in Fig. 2 could be induced again following the initial response by injections of 'Pitressin' 30 min later. It could be prolonged by giving the second injection 5 min after the first. Minimal flow rates were attained about 4 min after injection, and full restitution of bile flow was reached during the next 16–20 min. The pattern was the same in markedly overhydrated and in dehydrated animals, in spite of the fact that the preinjection level of the bile flow ranged between 8 and 12 $\mu\text{l./min}$ in the overhydrated group and between 1 and 3 $\mu\text{l./min}$ in the dehydrated animals. Animals were given 5–5 ml. of 12 per cent ethanol by stomach tube to inhibit secretion of antidiuretic hormone. These showed initial flow rates between 10 and 16 $\mu\text{l./min}$, which, however, responded to the pitressin in an identical manner to that described.

The rapidity of this response and its independence from the animal's state of hydration suggested that a smooth muscle coat was being constricted by the hormone. Wicks impregnated with the same hormone solution applied to the blood vessels of the liver had no effect on the bile flow*. By contrast, the usual response was elicited when these wicks were applied to the bile duct. Intravenous injections of 10 μg of L-epinephrine per rat or 1.6–2.4 mg of cyclic AMP (adenosine 3,5-monophosphate)^{2,3} induced the same response. This could be blocked by the local application of 'Novocaine' to the common bile duct. Indeed, the duct was found to possess a circular smooth muscle layer on histological examination. The sum of these observations was interpreted as indicating that the intravenously injected 'Pitressin' had caused a constriction of the muscular coat of the common bile duct proximally to the insertion of the catheter.

An additional hormonal action, namely on the reabsorption of water by the columnar epithelium lining these ducts, had been suggested by the results of the experiments with ethanol. Ballooned bile ducts could not be tested *in vitro*⁵. Therefore, evidence for water reabsorption was sought in intact animals by determining the osmolality of their bile. Two samples of bile from the ligated, ballooned bile ducts of two animals hydrated in the standard fashion showed 316 and 317 mOs/l. of bile respectively. Three samples were analysed from each of a

Fig. 2. Effect of intravenously injected 'Pitressin' on the bile flow of the rat

series of non-obstructed animals, as shown by the following means and standard deviations: dehydrated, 316 ± 6 mOs/l. (three animals); standard hydration, 298 ± 0 mOs/l. (four animals); water loaded, 276 ± 3 mOs (two animals). These preliminary results indicated that the osmolality of the bile did reflect the animals' state of hydration as had the bile flow. Furthermore, prolongation of the contact of the bile with the histologically intact epithelium of the ligated common duct appeared to result in more concentrated bile.

In summary, rapid sampling of rat bile showed the bile flow to oscillate. Intravenously injected 'Pitressin' induced a sharp diminution of the flow, which was ascribed to contraction of the smooth muscle surrounding the large bile ducts. In addition, there was collected suggestive evidence for a hormonal effect on the permeability of the bile ducts.

Alcohol and Evoked Potentials in the Cat

In our previous communication¹, we reported the relative effects of ethanol on the midbrain reticular formation and one site within the somatosensory cortex. It was found that the cortex was depressed by ethanol to a

greater degree than the reticular formation. Further investigations indicated that the response of the somatosensory cortex to alcohol depended essentially on the site of the recording electrode. In the earlier work the electrode was located on or near the coronal suture line for recording the cortical response on stimulation of the sciatic nerve. In the present report the electrode placement was in the region of the cruciate fissure.

Acute experiments were performed on healthy adult cats ranging in weight from 2.2 to 3.6 kg body-weight. Chloride silver ball electrodes (1 mm diameter) were placed under visual inspection in the region of the cruciate fissure with a medial location. The stereotaxic co-ordinates for the electrodes placed in the reticular formation were the same as described before. In each experiment, the electrode placements in the reticular formation were verified by histological examination of unstained frozen sections of the brainstem as described by Morillo and Baylor². Those experiments where the electrode placements were in doubt were discarded. In six animals the responses were recorded from the reticular formation at the mid-collicular level and the cruciate fissure of the somatosensory cortex contralateral to the stimulated sciatic nerve. In all the experiments following intravenous administration of alcohol (1 g/kg) both responses showed marked depression at 2 min. Recovery process was evident in each structure 15 min after alcohol administration. At 60 min the better part of the cortical response had recovered, but the reticular formation still exhibited marked degree of depression. Typical results of these experiments are shown in Fig. 1 which clearly indicate that the reticular formation exhibited a greater degree of depression throughout the entire period of observation.

The results are contrary to those presented earlier¹. The discrepancy was found to be due to the areas of recording sites in the somatosensory cortex. Moreover, experiments performed to examine the simultaneous effects of alcohol on the two cortical areas further reinforced the conclusion of the greater variability of the responses recorded from the coronal suture line as well as the lesser sensitivity of the cruciate site to the depressant effect of alcohol¹. Similarly the simultaneous responses of VPL and somatosensory cortex also disclosed that the cortical area was depressed as already described, whereas the VPL was scarcely affected by the dose of alcohol used in these studies. These results and those with two other sensory modalities (vision and audition) will be published in detail elsewhere. Obviously, the degree of depression of the somatosensory cortex by alcohol varies with the cortical

locus. Thus the relationship between reticular and cortical depression is a complex one and varies with the recording site in the somatosensory cortex.

Proposed Physiological Function for Plasma Cholinesterase

THE physiological function of plasma, or non-specific, cholinesterase, although receiving some attention¹, has not been established. This report deals with the possibility of its role as a regulator of free choline in the plasma. Several experiments were conducted *in vitro* to determine: (1) the inhibitory effects of free choline on the synthesis of acetylcholine and the activity of serum cholinesterase; (2) whether acetyl-S-coenzyme A (AcCoA) and choline acetylase were capable of synthesizing acetylcholine from another choline ester.

Rabbits were killed, and their brains removed and immediately dropped into liquid nitrogen. The brains were pulverized using a mortar and pestle at the temperature of dry ice. Acetone-cried powder was obtained by double extraction with cold acetone² and the choline acetylase was extracted by the method of Nachmansohn, Hestrin and Voripaieff³. Cholinesterase was prepared from horse plasma by the method of Oliver and Funnell⁴. Acetyl-S-coenzyme A was obtained from General Biochemicals, Ltd., Chagrin Falls, Ohio; propionylcholine iodide from Distillation Products Industries, Rochester, New York; and choline chloride from Anachemia Chemical Co., Toronto.

Solutions were prepared in Nachmansohn extraction buffer³, except that plasma cholinesterase was in *tris* buffer, pH 7.4. All reaction mixtures were made up to a final volume of 4 ml.

Acetylcholine formation was based on the change in absorbance at 232 mμ due to the hydrolysis of AcCoA⁵, and cholinesterase activity was determined by the method of Kellow and Lindsay⁶. In both cases, activity was measured at 26° C using a Beckman 'DK2' recording spectrophotometer. Propionylcholine was selected as the fatty acid choline ester because, at the wave-length used, its absorbance does not change with hydrolysis and of all those tested only its molar extinction was low enough to permit reliable interpretation.

In the first series, absorbance/time studies were made of the following reactions: (a) AcCoA + choline acetylase; (b) AcCoA + choline acetylase + choline; (c) AcCoA + choline acetylase + propionylcholine; (d) AcCoA + choline acetylase + propionylcholine + cholinesterase; (e) AcCoA + choline acetylase + cholinesterase. In each case, AcCoA was added at time zero.

A second series using AcCoA, choline acetylase and choline was carried out to determine the effect of varied choline concentration on acetylcholine formation. A third series using cholinesterase, benzoylcholine and varied choline concentration was investigated to find the effect of choline on the activity of cholinesterase.

Fig. 1. Evoked responses to electrical stimulation of the sciatic nerve recorded from the contralateral midbrain reticular formation (R.F.) and from the cruciate fissure in the somatosensory cortex (S.C.). A, Control; B, C, D and E, respectively, 2, 15, 30 and 60 min after intravenous administration of alcohol (1 g/kg). A depression in both responses is evident. (B) The reticular formation showing a greater degree of depression. Partial recovery of the cortical response can be seen at 60 min (E) while a marked depression still persisted in the reticular formation.

Trials (a), (c), and (e) of Series 1 showed that AcCoA was not hydrolysed when free choline was absent (Fig. 1). On the other hand, AcCoA was hydrolysed when choline was supplied directly (trial b) or indirectly through the action of cholinesterase on propionylcholine (trial d). The effects of varied concentrations of choline on the hydrolysis of AcCoA (Series 2) indicated that a peak activity occurred at approximately 10^{-5} M choline (Fig. 2). Cholinesterase activity was sensitive to a range of choline concentrations (Series 3) and, although inhibition was slight at 10^{-6} M choline, this inhibition increased to approximately 23 per cent at 10^{-3} M choline (Fig. 3)—the optimum concentration for acetylcholine formation (Fig. 2).

The results of Series 1 indicated that, at least for acetylcholine synthesis under the experimental conditions described, choline must be supplied in the free form. The concentration of free choline in the plasma of a number of species is held 'remarkably constant' at about 10^{-5} M (refs. 7 and 8) and increases in choline concentrations up to one-hundred-fold are followed by a rapid return to normal, partly through kidney excretion and partly due to a 'homeostatic mechanism'. Since, in the present study, the inhibition of plasma cholinesterase by choline occurred at a much lower concentration than the inhibition of choline ester synthesis (Figs. 2, 3), it is conceivable that serum cholinesterase could constitute a part of this homeostatic mechanism. That is, as the concentration of choline increases above the reported plasma concentration, 10^{-5} M, its return to within a normal range would be favoured by: (1) a decrease in choline ester hydrolysis caused by increased inhibition of cholinesterase; (2) an increase in choline ester synthesis caused by activation of the synthesizing mechanism, characterized in this study by choline acetylase and AcCoA. Both these effects would

Fig. 1. Re-drawing of hydrolysis curves obtained in Series 1. Reaction time 10 min

Fig. 2. Effect of choline concentration on acetylcholine synthesis. Velocity at 10^{-7} M choline expressed as unity

Fig. 3. Effect of choline concentration on cholinesterase activity. Velocity expressed as micromoles benzoylcholine hydrolysed per h

produce an increase in conjugated choline. Conversely, if the free choline concentration drops below normal, plasma cholinesterase activity is increased and esterification activity is decreased, thereby resulting in an increase in free choline concentration. Since a variety of choline esters occurs in plasma, the balance of conjugated/free choline could be maintained, in part, by the various isozymes of choline-, aliphatic-, and aryl-esterases^{9,10}, each utilizing a preferential choline ester substrate.

Thus, the homeostatic mechanism existing for the control of free choline in plasma⁷ may depend on two opposing systems, one (the plasma cholinesterases) responsible for choline ester hydrolysis, and the other responsible for choline ester formation; choline acts as an auto-regulator in the mechanism by its complementary effects on these two opposing systems.

Introduction of a Permanent Electrode into the Pituitary Gland of the Cow: Influence of Electrical Stimulation on Milk Ejection

PROCEDURES involving intervention with the pituitary gland or the hypothalamus, in the investigation of their influence on lactation, have mainly been carried out on small laboratory animals. Few experiments of this kind have been performed on ruminants; most of these were on goats and the remainder on sheep. This type of procedure has been extended to the cow by a process which we have described elsewhere¹. Essentially, the method consists of inserting a specially adapted needle through the skin and through the muscular part of the tongue to the pharynx, where the operating worker, with his hand in the oral cavity of the animal, places the tip of the needle in a defined position on the sphenoid bone. By means of

a drill which operates through the guiding needle, he drills through the sphenoid bone to the pituitary gland. In this way it is possible to carry out the application of various substances to the pituitary with the view of destroying it, or of carrying out biopsy of the pituitary gland, or of collecting blood from the sinus cavernosus.

In the next stage of our work we devised a method of introducing and placing permanent electrodes for direct stimulation. The electrodes used were made of platinum, or some other suitable metal, in the form of an insulated wire, which was conducted through a plastic cannula of polyvinylchloride and a cuff of stainless steel, and fixed in the sphenoid bone. The metal cuff was fixed in place with a ring of polyvinylchloride. The electrodes were passed through the application needle, which had the same diameter as the metal cuff of the electrode. The metal cuff, which was approximately 2 cm long, formed a continuation of the application needle, and with the aid of this needle it was firmly embedded in the sphenoid bone. When the electrode was so placed in the sphenoid bone it was not usually possible to pull it out. After fixing the metal cuff into the sphenoid bone, we pulled the wire carefully through the oral cavity, and with the help of a rubber probe we brought it out over the meatus nasi ventralis through the nostrils of the animal. Then we inserted a strong hypodermic needle into the wall of a nostril, in the free space between the cartilages parietales; we slid the wires leading to both electrodes through the needle, and after removing the latter, fastened the wires, which were taken out, with one or two stitches on to the skin of the regio lateralis nasi. It is possible to connect the stimulator here. Meanwhile, we controlled the exact placing of the electrodes radiographically and by dissection. The state of health of the animal and its physiological functions were not affected by the intervention, and the operation could be repeated at will.

A description of access to the pituitary gland of cattle was published by L. E. Donaldson and W. Hansel² and similarly of sheep by L. Z. McFarland, M. T. Clegg and W. F. Ganong³. In both cases access is over the foramen ovale. We consider that our way of reaching the pituitary gland is more reliable, because the needle introduced over the foramen ovale as a rule passes the pituitary gland at the posterior border.

We have used this method of stimulating the pituitary gland in connexion with further work on the neurohumoral regulation of lactation, particularly the mechanism of oxytocin action and ejection reflex. According to preliminary results, we have succeeded in inducing milk ejection by a series of square wave impulses. The mechanism of this effect is the subject of further investigation.

PHARMACOLOGY

Chloroquine Resistance and the Nature of Malarial Pigment

THE appearance of strains of human *falciparum* malaria resistant to chloroquine¹ has stimulated investigations on the mode of action of this drug and on the mechanism of resistance to it. Although no morphological differences have been described between chloroquine-resistant and ordinary *Plasmodium falciparum*, a striking difference was observed in the mouse malaria *P. berghei*; in the re-

sistant strain, pigment (haemozoin) was not visible by light microscopy, and even with the electron microscope only a few minute grains of pigment-like material could be detected². This finding and the hypothesis advanced independently by Seaueler and Cantrell³ and Cohen *et al.*⁴, that the binding of chloroquine by ferrihaemic acid might account for chloroquine resistance, direct attention to haemoglobin digestion and its waste product haemozoin as being possibly of significance in both the mode of action of chloroquine and in resistance to it.

Although haemozoin was described in 1847, before malaria parasites themselves had been seen, its chemical nature and its role in protein metabolism of the parasite are not well understood. Deegan and Maegraith⁵ showed clearly that haemozoin is not solely the iron protoporphyrin portion of haemoglobin, as had been naïvely assumed, but that it contains also a proteinaceous moiety. This conclusion was fully confirmed and extended by Sherman and Hull⁶. Since the terminology of derivatives of haemoglobin is a confusing one, as is well illustrated by errors in the recent literature (see following), some definitions are in order.

Haematin compounds are iron complexes of porphyrins and similarly constituted tetrapyrrolic substances. Porphin has the formula $C_{20}H_{14}N_4$ and contains 4 pyrrole-like rings welded together in a complicated ring system by 4 methene groups (Fig. 1a) (ref. 7). Haem is (ferrous) iron protoporphyrin IX, the designation IX indicating the side-chain configuration (Fig. 1b). Haematin, also called oxyhaemin, ferrihaemic acid or ferrihaem hydroxide (Fig. 1c), and haemin, or ferrihaem chloride, both have iron in the ferric state. Haemoglobin is a red conjugated protein of blood consisting of haem and a water-soluble protein, globin. On treatment with hot sodium chloride

1e. Hematinic acid

Fig. 1

and acetic acid it decomposes to yield haemin. Treatment of haemin with sodium hydroxide produces ferrihaemic acid (haematin, oxyhaemin or ferrihaem hydroxide), whereas treatment of haemin by dilute acids results in the removal of the iron giving protoporphyrin IX. If one hydrolyses haemoglobin carefully with hydrochloric acid the molecule is cleaved into 2 fragments: haemin (4 per cent) and globin (96 per cent). Drastic reduction of haemin with hydrogen iodide and red phosphorus gives a mixture of 4 pyrroles variously substituted with methyl and ethyl groups plus haematinic acid (Fig. 1e) (ref. 8). Oxidation of haemin with chromic acid yields haematinic acid⁹. The definitions and synonymy alone provide reasons sufficient for confusion.

Schueler and Cantrell³ have shown that ferrihaemic acid (haematin) can inactivate chloroquine to some extent both *in vivo* and *in vitro*, and on this basis have suggested that chloroquine-resistant parasites might produce more ferrihaemic acid than non-resistant strains. They state: "A singular intermediate product in the formation of malarial pigment is ferrihaemic acid (a ferrihydroxide form) which results from the oxidation and hydroxylation of haemin (a ferrous chloride form)". To our knowledge, ferrihaemic acid has never been identified as an intermediate in haemozoin formation (nor has any other intermediate been identified). Moreover, haemin is not a ferrous form (see foregoing definitions); only the haem as it exists in undenatured haemoglobin has iron in the ferrous state. The hypothesis that haemoglobin metabolism is somehow related to chloroquine resistance may still be correct. Certainly, the finding that chloroquine-resistant *P. berghei* produce very little, if any, haemozoin would fit this hypothesis. Unfortunately, however, too little is yet known to permit a detailed theory. In discussing the digestion of haemoglobin, Peters *et al.*² state: "It is possible that haemoglobin is split into globin and a porphyrin fraction, haem, although there is no direct proof that this is so. Haem is said to be oxidized first to haematinic acid and later to haematin, a toxic substance which is rendered both safe and insoluble by conjugation with a nitrogenous moiety to form the typical malaria pigment". They continue: "... workers have shown that haematinic acid can form a complex with chloroquine". Haematinic acid and ferrihaemic acid are not identical (see foregoing definitions), as these authors suggest. Furthermore, they state: "... the failure of RC (= chloroquine-resistant *P. berghei*) parasites to produce normal pigment ... can also be interpreted as a failure of the RC parasites to conjugate haematin with a nitrogenous moiety". Haemozoin is indeed a complex of haematin with a proteinaceous (perhaps denatured) moiety, but there is no shred of evidence that free haematin is ever formed.

What evidence there is indicates the contrary. Thus the early work of Moulder and Evans¹⁰ showed that extracts of *P. gallinaceum* contained a proteolytic enzyme capable of producing amino nitrogen from denatured haemoglobin. One of us (Sherman, unpublished results) has found a similar enzymatic activity in extracts of *P. lophurae*. Furthermore, amino-acid analyses of haemozoin of *P. lophurae* and *P. berghei* and of duck and mouse haemoglobins indicate that haemozoin is a product of partial proteolysis of haemoglobin (Tables 1 and 2).

For these analyses the avian malaria *P. lophurae* was isolated from duck red cells⁶, the free parasites lysed by alternate freezing and thawing the lysate centrifuged at 20,000*g* at 4° C for 1 h, the insoluble pellet (haemozoin) collected and washed three times in distilled water. *P. berghei* haemozoin was prepared from the livers of infected mice (7 days after inoculation) by grinding in a glass homogenizer followed by washing and collecting the insoluble residue by differential centrifugation. The isolation was followed by phase-contrast microscopy. Crystalline duck haemoglobin was prepared according to the method of Drabkin¹¹ and globin by the method of Anson and Mirsky¹². Haemozoin was cleared of colour

(removal of haem) and protein precipitated as described by Fulton and Grant¹³. Samples were hydrolysed and analysed for amino-acids according to the methods described for the Spinco 120B amino-acid analyser. Because the amino-acids found in crystalline duck haemoglobin were the same as duck globin it seemed unnecessary to prepare crystalline mouse haemoglobin. As can be seen from the figures in the last column, the amino-acids in haemozoin vary from those found in haemoglobin. The data are consistent with the idea that in the formation of haemozoin from haemoglobin there is: (1) denaturation and insolubilization of haemoglobin; (2) oxidation of the iron; (3) partial proteolysis of the globin. Haemozoin, although electrophoretically immobile on paper, stains with bromphenol blue⁶. In addition, the presence of amino-acids after extraction with trichloroacetic acid, ethanol and ether are definitive proof of its proteinaceous nature. This is true not only of the form from the red cells but also of that from the liver. Without the demonstration of plasmodial enzymes which break and reform haem to protein bonds it seems unlikely that haemoglobin is first split into haem and this then re-conjugated to another protein.

Haemozoin is not a chemically characterizable compound in a strict sense, and this property is reflected in varying amino-acid analyses. Although it is possible that adsorbed proteins may modify our results from isolation to isolation it seems more reasonable that the variations are real. We believe that the haemozoin one isolates is an array of partially degraded and denatured haemoglobins. These represent the point at which the investigator halted parasite proteolysis. Its amino-acid composition reflects the amino-acid sequence in the haemoglobin and the mechanism of cleavage of the haemoglobin by the plasmodial proteolytic enzymes.

Unfortunately, amino-acid changes from host-cell haemoglobin to haemozoin offer no real understanding of the kind and amounts of amino-acids used for parasite protein synthesis. In order to determine the amino-acids utilized, sequential analyses of substrate and residue are necessary as well as *in vitro* production of haemozoin by a

plasmodial proteolytic enzyme. The mechanism of chloroquine resistance may be related to ferrihaemic acid; but this has not been demonstrated, nor can haemozoin be called haematin, haematinic acid or ferrihaemate dimer. Reduced quantities of haemozoin in chloroquine-resistant strains of malaria cannot be due to ferrihaemic acid alone since the pigments are not identical.

This investigation was supported by a grant from the U.S. National Institute of Allergy and Infectious Diseases (AI 05226) and in part by a grant (AP 71-02) from the Division of Air Pollution, Bureau of State Services, U.S. Public Health Service.

Mepacrine- and Primaquine-resistant Strains of *Plasmodium berghei*, Vincke and Lips, 1948

THE demonstration that the mechanism of pigment formation in the rodent malaria parasite, *Plasmodium berghei*, could be disturbed when the parasites became resistant to the antimalarial drug, chloroquine^{1,2}, has since been confirmed by Thompson *et al.*³. The same phenomenon has now been described by Jacobs in a quinine-resistant strain⁴. In continuation of our own investigations we have developed two further strains of *P. berghei*, one of which, the *P* strain, has a high level of primary resistance to the 8-aminoquinoline compound, primaquine, and the second, the *M* strain, a high level of primary resistance to the familiar 9-aminoacridine derivative, mepacrine. The methods followed for the induction of drug-resistance in these strains and their subsequent testing for sensitivity to various drugs are identical to those used with the chloroquine-resistant (*RC*) strain and have been described elsewhere⁵. Preliminary examination of the ultrastructure of parasites of the *P* and *M* strains has been made in association with Dr. W. Stäubli, following the techniques already published².

Intraerythrocytic parasites of the 43rd passage of the *P* strain *P. berghei* survived in albino mice which received 30 mg/kg of primaquine diphosphate daily as a subcutaneous injection, for 55 days from the day of infection. In untreated mice the infection runs a slower course than that with normal (*N* strain) parasites. While the latter kill all untreated mice within 6-9 days, the animals may survive on the average from 14 to 19 days when infected with the *P* strain. The total dose of primaquine diphosphate (once daily subcutaneous for 4 consecutive days) which inhibits development of the *N* strain by 50 per cent, that is, the *ED*₅₀, is 9 mg/kg and the *ED*₅₀ is 24 mg/kg. The corresponding *ED*₅₀ of *P* strain passage 61 is 48

mg/kg while the *ED*₅₀ can be extrapolated graphically⁶ as approximately 400 mg/kg. A total dose of 1,650 mg/kg failed to eradicate parasitaemia from all mice infected with *P* passage 43, but permitted some of the animals to survive, presumably by giving them sufficient time to develop their own defence mechanisms. *P* strain *P. berghei* examined by light microscopy readily are seen to contain malaria pigment. The presence of pigment grains somewhat smaller than those of normal parasites was confirmed by electron microscopy which also demonstrated the presence in numerous trophozoites of more than one food vacuole, a feature we have previously associated with our chloroquine-resistant *RC* strain². Some difficulty was experienced in preparing ultra-thin sections in which this pigment was demonstrable since, although we used the identical technique with which we had previously been able to show the presence of normal haemozoin², the *P* strain pigment dissolved out very readily during the standard staining procedures. The pattern of cross-resistance of our *P* strain is still being investigated. Preliminary studies show that the trophozoites are resistant to the dihydrotriazine metabolite of proguanil (as we had earlier observed when testing our 'triazine'-resistant *B* strain of *P. berghei*⁶). The *P* strain also exhibits resistance to pyrimethamine, while sensitivity to chloroquine and mepacrine so far is within normal limits. Details of these tests will be published elsewhere. The resistance to primaquine is unstable and some change towards normal sensitivity to this compound was noted in parasites passaged from an untreated 14-day-old infection with *P* passage 43 into clean untreated mice. During the course of the infection in the donor mice the pigment granules, as seen by light microscopy, appear to become darker and somewhat larger from about the fourteenth day of infection onwards.

M strain parasites show a similar level of resistance against mepacrine methanesulphonate. The *ED*₅₀ and *ED*₉₀ of the *N* strain for this compound are 15 and 26 mg/kg respectively. Parasites of *M* passage 32 continued to develop in mice treated with a subcutaneous dose of 50 mg/kg mepacrine methanesulphonate daily for 14 days from the day of infection, a total of 700 mg/kg. (At this point all the mice succumbed to overdosage of the drug.) Parasites of *M* passage 44 survived in several of a further group of mice given 30 mg/kg subcutaneously for 35 days or a total of 1,050 mg/kg. By light microscopy the *M* strain trophozoites and schizonts present a very similar appearance to that described for chloroquine-resistant *P. berghei*². No pigment grains are seen in parasites in mepacrine-treated mice. Granules (0.03-0.07 μ mean diameter) within the cytoplasm of the parasites can be demonstrated by electron microscopy. Normal pigment grains measure 0.1-0.3 μ (ref. 2). Multiple food vacuoles are also common and afford a further point of similarity between this and our *RC* strain. *M* strain parasites on preliminary testing have been found to be resistant also to chloroquine and quinine but sensitive to primaquine, pyrimethamine, 'triazine', sulphadiazine and diaminodiphenylsulphone. The resistance to mepacrine is extremely labile. Pigment reappeared by the end of 7 days in untreated mice infected with *M* passage 44. At the same time, the parasites reverted to a normal sensitivity to mepacrine.

In an earlier note¹ I suggested that my observations on pigment changes associated with the development by *P. berghei* of resistance to chloroquine could afford supportive evidence for the hypothesis of Schueler and Cantrell⁷ and Cohen, Phifer and Yielding⁴. I thank Prof. Yielding (personal communication) for pointing out an error in my terminology. All references to 'haematinic acid' should have read 'ferrihaemic acid'. Deegan and Maegraith in 1956 (ref. 9) suggested that malaria pigment consists of the porphyrin, haematin, combined with a nitrogenous moiety. In the preceding communication Sherman, Mudd and Trager¹⁰ now confirm that the

haemozoin of normal *P. berghei* is a heterogeneous mixture of porphyrin-peptide compounds derived from the degradation of the host erythrocyte haemoglobin at various points in its chain by proteolytic enzymes of the parasite. Whether a part of the haemoglobin is completely degraded in the process to yield a soluble porphyrin is not known but would not be beyond the realms of possibility. The work of Ball *et al.*¹¹ with *P. knowlesi* would, however, suggest that, at least in this species, "the parasite retains within its cell all of the heme that it splits off from hemoglobin". (These authors were, of course, of the then current opinion that the porphyrin and globin portions were completely split by the malaria parasite.) It is difficult to visualize, therefore, how such a mechanism as complexing of antimalarial drugs by ferrihaemic acid can account for the development of drug resistance by *P. berghei* although it may play a part once resistance has developed. If, then, free porphyrin is released by the parasite following the more complete digestion of haemoglobin in the food vacuoles that apparently occurs in our *RC* and *M* and Jacobs's⁴ quinino-resistant strains, it might conceivably inactivate some of the drug with which it is in contact in the artificially high concentration that is used in such experimental conditions in mice. Some other, so far undefined mechanisms must underlie the ability of the parasites to survive such a normally lethal environment. This order of drug concentration is certainly never likely to be encountered in the human subject with *P. falciparum* malaria.

Of immediate practical importance is the possibility that primaquine may prove to be relatively ineffective for the treatment of infection by other species of malaria parasites such as *P. falciparum* that are resistant to pyrimethamine, proguanil or its dihydrotriazine metabolite.

HAEMATOLOGY

[Haptoglobin Johnson in Australian Aborigines

THE rare haptoglobin phenotype, Johnson, discovered by Giblett¹ in a Negress and her daughter, has since been described in Chinese, Jewish and Caucasian populations². During the course of a population study of the blood groups and serum proteins of Australian Aborigines of Central Australia³, two sera taken from members of the Pintubi tribe were found to have this phenotype. Afterwards, samples from the family of one of these were obtained. While there is some White admixture among Central Australian Aborigines, the propositus himself is, so far as can be ascertained from his blood groups and general appearance, wholly Aboriginal.

The haptoglobin phenotypes of the members of the pedigree are indicated in Fig. 1. The starch-gel pattern designated H (for hypohaptoglobinaemia) was very similar to that of the serum of a member of the pedigree reported by Ramot *et al.*⁴ in which the parents were also Hp 2-1

Fig. 1. Pedigree of an Australian Aboriginal family involving the Johnson haptoglobin type

and Johnson. Their pedigree and that reported here are in agreement with the previously proposed hypothesis⁵ that Johnson is genotypically $Hp^{2J}Hp^1$. Further, both pedigrees agree with the suggestion⁴ that the genotype $Hp^{2J}Hp^2$ is either hypohaptoglobinaemic or ahaptoglobinaemic.

We thank Dr. R. L. Kirk for confirming our Johnson typing and for the gift of a Johnson reference sample. We also thank Mr. H. C. Giese, director of Welfare, Northern Territory Administration, for his kindness in facilitating visits to Papunya, and to the Australian Institute of Aboriginal Studies for a grant in support of this investigation.

Low Concentrations of Serum Haptoglobin in Mothers of Children with Haemolytic Disease of the Newborn

THE ante-partum prognosis of foetal haemolytic disease is very difficult. The presence and titre of antibodies discovered in pregnancy are not always comparable with the seriousness of the clinical manifestations in the newborn; in the case of an incompatibility in the ABO system not even this guide is available, so that for this purpose new methods are persistently being sought¹.

In foetal erythroblastosis the foetus is attacked by antibodies. The damage found after delivery varies in degree from anaemia² to hydropic foetus and, in the extreme, to stillbirth. The disintegration products of foetal erythrocytes are supposed to be transported out of the foetus by the placenta. The transmission of unconjugated bilirubin through the placenta was directly shown by Schenker *et al.*³ in the guinea-pig foetus. This is compatible with placental transmission of free haemoglobin molecules, which obviously represent the main fraction of the foetal extracorporeal haemoglobin in the absence of haptoglobin—traces of which are only seldom found in the cord blood by special methods⁴. The transmission of free foetal haemoglobin into the maternal

* Not obtained.

circulation ought to be followed by a depression of the serum haptoglobin concentration according to Laurell and Nyman⁵, and as suggested by certain haemolytic disorders⁶.

The present experiments were designed to show whether there is a lower serum haptoglobin level in mothers whose children were to be treated by exchange transfusion, as compared with the mothers of healthy children. The blood samples were collected within a day post-partum. The second sample was drawn from each mother six days after delivery, that is, when the haptoglobin eliminated as a complex with haemoglobin would be fully replaced⁵. The haptoglobin concentration values obtained by three repeated determinations by the method of Owen, Better and Hoban⁷ are shown in Table 1 according to the haptoglobin serum groups identified by starch-gel electrophoresis.

Six days after parturition all the haptoglobin values are significantly elevated ($t = 9.73$ for $v = 15$) without significant difference between affected mothers and controls.

The mean haptoglobin values of the samples collected in the first 24 h post-partum are not significantly different in the unclassified populations, or in the groups Hp (2-1). Comparison of the haptoglobin concentration values of the group Hp (2-2) sera, however, shows a lower mean value in mothers whose children, suffering from a haemolytic disease caused by an incompatibility of the blood groups in the ABO or Rh systems, were treated by exchange transfusion. The statistical significance of the difference was confirmed by an analysis of variance.

With respect to the elevation of the haptoglobin concentration after delivery, previously observed by Lacomme⁸, the lower haptoglobin concentration values found immediately after delivery may be regarded as a persistence of the lower haptoglobin level in the prenatal period. The haptoglobin concentration values in the group Hp (2-1) cover a wide range. According to Nyman⁵, the dispersion is as great as that of the whole unclassified population. This is presumed to be the reason for the non-significant results (above) in the whole population and in the group Hp (2-1); the greater homogeneity on a lower level of haptoglobin concentration values of the sera of the Hp (2-2) group⁹ would be the reason why these showed a significant difference. The depression of the haptoglobin is evidently caused by the same factors as were noted in the experiment of Laurell and Nyman⁵ and in some haemolytic disorders⁶. Changes in the haptoglobin concentration may prove to be of greater diagnostic and prognostic value than the concentration of extracorporeal haemoglobin itself, which is permanently eliminated from the circulating blood in the form of a haptoglobin-haemoglobin complex, while the formation of haptoglobin is not accelerated by saturation of haptoglobin by haemoglobin only¹⁰.

The results described here serve as a starting point for a more detailed investigation of the individual haptoglobin concentration changes in the prenatal period.

HISTOCHEMISTRY

Cholinergic Excitation and Inhibition in the Cerebellar Cortex

The cholinergic character of mossy fibres and especially that of their endings in the parenchyma islets of the cerebellum has been repeatedly demonstrated both biochemically¹ and histochemically²⁻⁶. There is also evidence for the cholinergic nature of Golgi axons, synapsing with granule cell dendrites in the cerebellar glomeruli⁷, although it appears that at this site an adrenergic mechanism is involved as well. The experiments reported here were performed on the cerebella of guinea-pigs; they suggest that cholinergic mechanisms are involved both in the parallel axon-Purkinje dendritic spine synapses (regarded as excitatory junctions⁸) and in the basket axon-Purkinje cell-body synapses (supposed to be inhibitory in their character⁹).

The photomicrographs (Figs. 1, 2 and 3) were obtained from sagittal and frontal sections of the guinea-pig cerebellum, stained for acetylcholinesterase according to the Gerebtzoff modification of Koelle's thiocholine technique. It appears that the entire length of granule cell axons (both the ascending parts and the T-shaped bifurcated branches) displays acetylcholinesterase activity, most marked at the varicosities (beads) of these fibres, which are supposed to synapse with Purkinje and Golgi dendritic spines. Phase-contrast microscopy actually reveals the presence of cholinesterase-negative dendritic spines intruding the enzyme-active axons. On the other hand, there is a major concentration of enzymatically active nerve fibres at the bases of Purkinje cell bodies, eventually becoming arranged

as a cuff around the origin of the Purkinje axon. These structures are undoubtedly identical with the 'basket-formations' of the inner stellate (basket) cells. The acetylcholinesterase activity of the parenchyma islets (glomeruli) consisting of axonic endings of mossy fibres and Golgi cells, and of the short dendritic branches of granule cells, show an acetylcholinesterase activity similar to that already described in the rat, rabbit and cat. The climbing fibres, around the primary and secondary Purkinje dendrites, can also be identified as strongly acetylcholinesterase-active structures.

It appears, therefore, that in the guinea-pig, all synapses in the cerebellar cortex are operated by a mechanism involving acetylcholinesterase activity. It should be stated that we have found (unpublished) that at all these synapses the enzyme is located presynaptically, as are also the synaptic vesicles in these junctions. Assuming that the presence of synaptic vesicles and of acetylcholin-

esterase proves a cholinergic mechanism, it would appear that both the excitatory synapses (mossy fibre-granule cell; parallel axon-Purkinje dendrite; parallel axon-Golgi cell; parallel axon-basket cell; climbing fibre-Purkinje dendrite) and the inhibitory junctions (Golgi axon-granule cell; basket axon-Purkinje cell) are operated by the same chemical mediator substance. This, in turn, would indicate that—at least in the cerebellar cortex—it is not the chemical structure of the mediator substance, but rather the molecular structure of the underlying post-synaptic membrane that is responsible for the excitatory or inhibitory effect of the nerve impulse.

PATHOLOGY

Immunological Tests in Helminthic Diseases

THERE is an increasing tendency to use immunological tests when considering helminthic diseases to avoid the difficulty inherent in the finding of the worm or its ova. Though such a procedure is obviously of value both in epidemiology and in clinical investigations, it seems necessary to sound a word of caution in interpretation.

It should not be necessary to point out that different parameters are being measured, and that, in fact, they are in some cases estimating factors in opposition. Whatever technique is being used to estimate the immune response the latter is likely to be paralleled to some extent, however minor, by a protective mechanism.

Theoretical considerations reveal some interesting phenomena which must be taken into consideration in survey work of any kind, and in the clinical interpretation of immunological results.

If a is the proportion of a population infected in unit time, and b that of individuals escaping, then the age-distribution of infections will be the expansion of the binomial $(a+b)^t$. Thus, the proportion of individuals infected at age t will be $1-b^t$, but of these a^t will have been infected t times, ta^{t-1} will have been infected $t-1$ times, and so on.

If we make the not unwarranted assumption that the acquisition of protection is some function of the number of infections and their duration, we can derive a series of curves reflecting the age distribution of apparent infection in a population. Fig. 1 shows the time-distribution curve of manifestation for an endemicity of $a = 0.20$ and for several values of w , which may be defined as the parasitoduration required to induce protection. The smaller the value of w , the greater the immune response, and where $w = \infty$ there is no development of immunity. Superimposed is the proportion of protected (immune) individuals.

The similarity of the 'manifest' curves to the age-distributions obtained for many parasites is immediately apparent; on the other hand, the proportion of immunes,

Fig. 1. Sagittal section of guinea-pig cerebellum. Acetylcholinesterase reaction, pH 5.8. Incubation, 2 h. Cell bodies and dendrites (arrows) of Purkinje cells (P) are unstained, whereas the vast amount of parallel fibres (cut transversely) react strongly. Double arrow, secondary dendrite; triple arrow, tertiary dendrite. Note the dendritic spines (non-reacting) of the tertiary dendrites, surrounded by heavily stained parallel fibre junctions.

Fig. 2. Coronal section of guinea-pig cerebellum; acetylcholinesterase reaction, pH 5.8. Incubation, 1 h. Note the strongly reacting basket cell endings (arrows) at the bases of the unstained Purkinje cells (P). In the molecular layer (M) parallel fibres are stained.

Fig. 3. As Fig. 2, but pH 5.2. Note the strong reaction of the basket-cell 'cuff' (arrows around the axon origin of the Purkinje cell, P).

Fig. 1. Effect of differing immune pressure on manifestation

Fig. 2. Effect of differing endemicity on manifestation

presumably parallel to those detected by immunological tests, follows an entirely different curve, emphasizing the fact that not only are different parameters being measured, but also that they are, at greater values of t , operating in opposition.

Though this concept should be obvious, many investigators are assessing the value of this, that or the other immunological approach by comparison with the finding of ova or the like.

A further startling fact is shown by Fig. 2, which shows the curves, derived by applying different endemicities (values of a) to the same protection pressure. It will be seen that the higher the endemicity the lower the incidence at longer exposures. This merely re-emphasizes the caution required in interpretation of survey figures. If, for example, the presence or number of ova is being used as a parameter, then examination of too old an age-group would give an entirely fallacious estimate of endemicity. On the other hand, the presence of immune bodies might be a better measure.

To clinicians, this hypothesis is an additional warning to treat the parasite and not the immunological test.

These considerations do not take into account such phenomena as immune tolerance or antibody saturation, both of which may have to be considered in the interpretation of survey results.

I thank J. de V. Clarke, of the Bilharzia Research Laboratory at Salisbury, for the stimulus which provoked these thoughts.

Lymphatic Neoplastic Transformation of Thymus in Mice with Myeloid Virus-induced Leukaemia

In a recent study¹ it was found that in mice of certain strains inoculated with Graffi virus, removal of thymus had practically no effect in modifying the incidence of leukaemia while it favoured to a considerable extent the shift of neoplastic transformation from lymphoid to myeloid tissues. In addition, it was noted that in intact mice with generalized myeloid leukaemia the thymus appeared free from disease, or in some cases showed leukaemic changes of the lymphatic type. It was then considered of interest to study more systematically the morphology of thymic tissue in animals which developed myeloid leukaemia following inoculation of Graffi virus at birth.

C57BL mice received subcutaneously, within 48 h after birth, 0.05 ml. of cell-free extract containing Graffi virus, prepared as previously reported¹. They were observed for development of leukaemia and killed when moribund. Among the 61 leukaemic mice examined both histologically and haematologically, the type of leukaemia was lymphatic in 35 and myeloid in 26. Mice with myeloid leukaemia showed grossly in nearly all cases a characteristic green colour of the enlarged lymph nodes, while the thymus appeared pearly white and normal or slightly increased in size. The difference in colour was useful in outlining the contour of the whitish thymus surrounded by the green mediastinal lymph nodes.

Of the 26 mice with myeloid leukaemia five had atrophic thymus, composed of non-neoplastic lymphocytes. In the other 21 cases the thymus was involved by the leukaemic process, but the type of neoplastic cells replacing thymic tissue was clearly lymphoid. Thus, tumour tissues of both lymphoid and myeloid type were microscopically recognizable side by side, separated only by the thin capsules of mediastinal nodes and thymus (Figs. 1a and b).

Figs. 1a and b. Myeloid leukaemia with lymphatic neoplastic transformation of thymus. Medial lymph nodes on left, thymus on right. (Haematoxylin-eosin, a, $\times 60$; b, $\times 200$)

In mice with lymphatic leukaemia, thymus appeared markedly enlarged and showed neoplastic lymphoid changes indistinguishable from those observed in the other organs involved.

The autonomous neoplastic transformation of thymus in myeloid leukaemia induced by Graffi virus was also confirmed in another series of experiments to be reported in detail elsewhere. Virus-injected thymectomized ($C3Hf/Gs \times CBA/H-T6T6$) F_1 mice bearing subcutaneous thymus graft from normal new-born $C3Hf/Gs$ donors developed either lymphoid or myeloid leukaemias. In a small number of these animals with myeloid leukaemia, the grafted thymus exhibited neoplastic modification of the lymphoid type. The co-existence of two different neoplastic tissues was further proved by the successful transfer of lymphoid thymus and myeloid nodes from the same leukaemic animal to syngeneic mice, leading to local development of both lymphoid and myeloid growths.

Subsequent or simultaneous proliferation of two different types of haemopoietic tissues has also been described in other leukaemic murine diseases²⁻⁴. However, on the basis of these results, it would seem that the thymus has a peculiar cytological character such that leukaemic transformation within this organ is restricted to the lymphoid cell-type.

IMMUNOLOGY

Histocompatibility Antigens in Transplanted Mouse Eggs

THE hypotheses advanced to account for the success of the foetus as an intra-uterine homograft in pregnancy have recently been reviewed by Billingham¹. Three possible mechanisms have been suggested to explain the apparent lack of immunological reaction by the pregnant mother against the genetically foreign offspring with which she is in intimate contact²: (a) the antigenic immaturity of the foetus; (b) the immunological inertness of the mother; and (c) some form of anatomical separation of the foetus from the mother. It has, however, been shown that transplantation antigens appear early in embryonic life and that the mother, though pregnant, is fully capable of reacting against these antigens³⁻⁵. In addition, it has been shown that the uterus is not a specially privileged recipient site for prolonged homograft survival^{6,7}.

We have previously suggested that the trophoblast may be an immunologically privileged anatomical barrier between mother and foetus, ensuring foetal survival^{8,9}. Fertilized hybrid mouse ova were transplanted heterotopically beneath the renal capsule of recipients of the maternal strain. In this site, the ova developed into agglomerates of trophoblastic giant cells which did not provoke demonstrable specific sensitivity to subsequent paternal skin grafts. In addition, trophoblastic proliferation did not seem to be inhibited even when the recipients had previously been immunized by paternal skin grafts.

The present experiments were designed to elucidate further the previously postulated deficiency in effective histocompatibility antigens in mouse trophoblast. Ova, derived from inbred matings, homozygous with respect to histocompatibility antigens, were transplanted into highly immunized recipients.

The mice used were of the inbred strains, $C3H/HeJ$ and $C57BL/6$, obtained from the Jackson Memorial Laboratories, Bar Harbor, Maine. Adult male $C57$ mice were divided into three experimental groups of recipients. Group I received no treatment prior to ova transplantation; the animals in Group II were grafted with full-thickness $C3H$ skin grafts by the standard method of Billingham and Medawar¹⁰; transplants of ova were carried out one to two months after these skin grafts. The animals in Group III received two consecutive full-thickness $C3H$ skin grafts, with an interval of three weeks between grafts; in addition, these animals received 8-12 weekly intraperitoneal injections of 25-30 million dissociated spleen cells. Ova transplants were performed less than one week following the last injection. A fourth group of syngeneic recipients consisted of $C3H$ adult male mice.

Fertilized $C3H$ ova were expressed from the oviduct 1½-2½ days post-coitus as previously described⁸. Two ova were individually placed beneath the capsule of each recipient $C57$ kidney through a finely drawn Pasteur pipette. Both kidneys were routinely used, each recipient thus receiving four ova. Ten days after transplantation, the animals were bled, and the serum was collected and frozen. Haemagglutinin titres were later carried out by the method of Stimpfling¹¹. All animals were then killed, and the kidneys were inspected for haemorrhagic tumours characteristic of trophoblastic proliferation. All suspect areas were removed for individual histological study; the tissues were fixed in formalin, embedded in paraffin and sectioned at 7µ. Haematoxylin and eosin staining was normally performed.

The results are summarized in Table 1. Trophoblastic tumours were found in most (80 per cent) of the previously untreated $C57$ recipients of $C3H$ ova as well as in 84 per cent of the syngeneic recipients. Histologically, these haemorrhagic tumours consisted of abnormally large trophoblastic giant cells with vesicular nuclei. There was a marked haemorrhagic reaction, host blood filling the intercellular spaces of the cellular network.

Table 1. TROPHOBLASTIC PROLIFERATION FROM FERTILIZED $C3H$ MOUSE OVA IN IMMUNIZED AND NON-IMMUNIZED MALE MICE

Recipient animal	Immunization	No. recipient animals	No. animals with trophoblast	Titre anti- $C3H$ haemagglutination
$C3H$ male	None	19	16	<1/20
$C57$ male	None	20	16	<1/20
$C57$ male	One $C3H$ skin graft	19	5	<1/20
$C57$ male	Two $C3H$ skin grafts and 8-12 $C3H$ spleen cell injections	16	0	1/80-1/640

Only 25 per cent of the $C57$ male mice which had previously rejected one $C3H$ skin graft supported $C3H$ trophoblastic proliferation under the kidney capsule. Histologically, these growths did not differ significantly from those grown in unsensitized recipients. A characteristic inflammatory response involving mononuclear cells was not consistently present. There was no detectable haemagglutinating activity in the sera of untreated and singly skin-grafted recipients.

No evidence of trophoblastic proliferation could be found ten days after $C3H$ ova implantation into those $C57$ recipients hyperimmunized by $C3H$ skin grafts and multiple $C3H$ spleen cell injections. In these, haemagglutinin titres ranged from 1:80 to 1:640.

Several investigators have shown that the ectopic implantation of fertilized mouse ova results in the proliferation of trophoblastic tumours even in xenogeneic combinations¹²⁻¹⁴. We have previously demonstrated

that proliferation of hybrid (*CBA* × *A*) mouse trophoblast is possible in mice of the maternal strain (*CBA*) which have previously rejected paternal (*A*) skin grafts. In order to determine if this failure of antigenic expression was due to an absolute deficit of antigens or to some other characteristic of trophoblastic growth, the present experiments utilized inbred ova homozygous with respect to histocompatibility determinants. In addition, implants were made into recipients hyperimmunized against the histocompatibility antigens of the parental donor with resulting high titres of haemagglutinin activity. A definite inhibition of trophoblastic growth was observed and was proportional to the degree of pre-existing immunity. It is therefore apparent that histocompatibility antigens are present in trophoblast or in the pre-trophoblastic tissues of ectopically implanted mouse ova.

Quantitation of the number of antigenic determinants per cell, or per square unit of cell surface, is, of course, beyond the reach of the present techniques. Nevertheless, the likelihood of a relative deficiency in the expression of histocompatibility antigens in trophoblast, as compared with other tissues, still appears to be substantial from the present extension of our previous experiments. The fact that homozygous donor cells were used in the more recent experiments makes it possible that their more obvious susceptibility to appropriate prior sensitization may reflect a gene-dose effect.

RADIOBIOLOGY

Tests on *Drosophila* for the Production of Mutations by Irradiated Medium or Irradiated DNA

(1) *Irradiated medium.* Ionizing radiations are likely to find increasing use in industry for prolonging the useful storage-life of food. Before the method is declared safe and becomes widely acceptable, however, it is necessary to ensure that consumption of irradiated food is free from genetic ill-effects. Mutation rates have been shown to increase when bacteria are grown in ultra-violet-irradiated substrate¹. Bacterial medium irradiated with ionizing radiations, however, has not been tested for its mutagenic effects. Information about the indirect genetic effects of ionizing radiations in higher organisms is scanty. Investigations of the cytological effects in root meristems of plants grown in X- and γ -ray irradiated potato mash² and fruit juices³ have shown that the aberration frequencies in treated roots were strikingly higher than in corresponding controls. In order to test for similar effects in animals, these studies were extended to *Drosophila*. It was found that the rate of sex-linked lethals was increased

slightly, but significantly, in the progeny of flies raised on irradiated food⁴. In view of the obvious importance of this observation it was thought necessary to re-test it, scoring both autosomal and sex-linked lethals. The former were included because it has been shown^{5,6} that feeding of unirradiated calf thymus DNA has a very specific and pronounced mutagenic effect on chromosome II of *Drosophila*, while the X-chromosome remains largely refractory to this treatment. Induced dominant lethality was also investigated in view of the chromosome breakage observed in plant material grown on irradiated medium. The results of these investigations are reported in this communication.

Food consisting of 10 per cent dried killed yeast, 10 per cent sucrose and 3 per cent agar in water was irradiated by the Radiation Research Laboratory, Wantage. The total dose of 1 mrad of γ -rays was delivered in a single exposure lasting 70 min from a 14,000-c. annular cobalt-60 source. The Oregon-K (Or-K) stock for these experiments has been used in this laboratory for mutation experiments for a long time and has shown a spontaneous rate of about 0.3 per cent sex-linked lethals in periodic checks. In the first experiment 24- and 48-h-old larvae were transferred to the irradiated food about 36 h after the termination of radiation exposure, and the frequency of sex-linked and second chromosome (autosomal) lethals was determined simultaneously in both treated males and females. In order to keep the experiment manageable and because of the known spontaneous mutation rate of the stock, controls were not included in this experiment. In a second experiment the usual maize meal-molasses food was used. Young Or-K females, mated 24 h earlier, were transferred to the irradiated food for egg laying immediately on termination of the irradiation exposure, so that the developing flies should be exposed to the full effect of the treatment including that due to any transient radicals. Males which had developed on irradiated food were tested for sex-linked lethals. Comparable controls were included in this experiment. Scoring was done by the usual techniques, namely, hatchability for dominant lethals, Muller-5 test for sex-linked lethals and *Cy/L* test for second chromosome lethals.

The results are summarized in Table 1. Since no difference was found between 24- and 48-h old larval transfers, data from these two sets of the first experiment have been pooled. It will be seen that the values for sex-linked lethals in experiment 1 are within the range usually found for the stock used. Those for autosomal lethals are twice as frequent, and this is as expected from the length relationship between the X- and the second chromosome. No difference apart from that inherent in the difference of sex⁷ was observed in tests on treated males and females, thus ruling out any influence of germinal selection against sex-linked lethals in the hemizygous males. Tests for dominant lethality, replicated twice, likewise gave entirely negative results, the mean percentage of hatchability in control and treated series being 87.7 and 87.2 respectively. In the second experiment a higher mutation rate might have been expected because of the action of transient radicals which would have been missed in the first experiment. Actually, mutation frequency was even lower here than in experiment 1 and not higher than in the controls.

These experiments, therefore, do not provide any evidence for a mutagenic substance being produced in irradiated food. Similar negative results have been

Table 1. FREQUENCY OF LETHALS IN *Drosophila melanogaster* RAISED ON IRRADIATED OR UNIRRADIATED FOOD

Experiment No.	Sex of the treated flies	Chromosome	No. of chromosomes tested	Lethals (%)
1	Males	X	1,653	0.256
		II	1,438	0.556
	Females	X	1,458	0.137
		II	1,378	0.290
2	Males	X (treated)	2,044	0.097
		X (control)	1,328	0.150

obtained by Moutschen (personal communication). On the other hand, Swaminathan *et al.*⁴ and more recently Rinehart (personal communication) have obtained small, but statistically significant, increases of mutation rates in *Drosophila* raised on irradiated food, indicating that in certain circumstances marginal effects in mutation rate may be produced. In contrast to this, the previously mentioned experiments on plant chromosomes had shown a striking increase in the frequency of chromosome breaks in root meristems of wheat and barley grown on irradiated water⁵, potato mash² and fruit juices³. The difference between the striking cytological effects in plants and the marginal effects in *Drosophila* may be due to some basic differences in the two systems. Obvious among these are: (1) In plants the treatment is applied directly to the tissue in which the effects are looked for, so that the cells can take up the reactive principle fairly quickly and without its undergoing metabolic changes. In feeding experiments with *Drosophila*, on the other hand, the irradiated food has to undergo a series of metabolic changes in the digestive system of the fly. The radiomimetic principle produced by irradiation will thus reach the gonads in a greatly modified form which may be mutagenically ineffective. (2) While chromosome breaks in plants are scored in cell cycles immediately following the treatment, *Drosophila* germ cells are sampled many cell generations after treatment. Also, aberrations in treatments with fruit juices consisted entirely of chromosome breaks and no evidence for translocations indicating rejoining was obtained. Such chromosome breaks, if induced in *Drosophila*, can produce dominant lethals only, and these, if produced in pre-meiotic cells, are likely to be eliminated during meiosis. In order to create experimental conditions for *Drosophila* that are more similar to those used in plants, one might determine dominant lethals in mature sperms of adult *Drosophila* males that have had irradiated glucose or fruit juices administered to them by drinking or injection. Experiments on these lines have now been started.

(2) *Irradiated DNA*. While these experiments on the effect of irradiated food were in progress, Parkash published results of an experiment in which 1.8 per cent of irradiated fish sperm DNA had been mixed into the food of *Drosophila* larva. The emerging males had 36 lethals in 635 tested X-chromosomes, a frequency of 5.7 per cent⁶. In a second experiment¹⁰, 9.6 per cent autosomal lethals were obtained, but there was no control and it is not clear whether pre-existing lethals had been excluded. This seemed such a striking and important observation that I repeated the experiment, using herring sperm DNA but otherwise the same procedure as Parkash. The irradiation with 100,000 r. of γ -rays was performed by the Radiation Research Laboratory, Wantage (exposure time 31 min). The irradiated DNA was mixed with *Drosophila* food, and Oregon-K flies were allowed to feed and lay eggs on this food. Food mixed with unirradiated DNA served as control. Males that had developed on DNA-treated food were tested for sex-linked recessive lethals according to the Muller-5 method. The experiment was repeated thrice with negative results. In a total of 5,705 control and 5,762 treated chromosomes the percentage incidence of sex-linked lethals was 0.29 and 0.35 respectively. Dr. Parkash (personal communication to Dr. C. Auerbach) suggested that the discrepancy between our results might be due to the difference in medium used. Because of a possible competition between the irradiated DNA and the nucleic acids of yeast, he had prepared his medium entirely without yeast, according to the following formula: sugar, 7 g; bran, 7 g; maize meal, 6 g; and agar, 0.8 g; cooked in 100 ml. water. Another experiment was carried out, using the aforementioned formula. The rest of the experimental procedure was the same as described earlier. The development of the flies on this food was considerably delayed, first emergence taking 14 days as against 9–10 days at 25° C on the food used in this laboratory. In

1,089 chromosomes from 91 males developing on food mixed with unirradiated DNA and 2,220 chromosomes from 167 males developing on food containing irradiated DNA, the percentage of sex-linked lethals was 0.18 and 0.22 respectively. My experiments therefore give no support to the conclusion that, in general, irradiated DNA is mutagenic for *Drosophila*. It is difficult to visualize which special conditions led to the positive results in the experiment carried out by Dr. Parkash.

I thank Dr. C. Auerbach for her advice. This work was undertaken during the tenure of a Commonwealth scholarship.

Mutagenic Effect of Irradiated and Unirradiated DNA in *Drosophila*

THE treatment of food with ionizing radiation is known to be an effective means of prolonging the useful storage-life of food. However, in view of the possible health hazards which might be involved in the treatment of food with ionizing radiation, a working party, appointed by the Ministry of Health, has evaluated the possible dangers, and the controls required, in the use of ionizing radiation for this purpose¹.

One consideration of importance is the possible production of chemical mutagens by the action of the ionizing radiation on the food material¹. The available evidence for a mutagenic effect of irradiated food on animal tissues is based on experiments where *Drosophila* larvae have been cultured on a medium which has previously been exposed to a heavy dose of ionizing radiation. Although it has been reported² that there is a slight, but significant, increase in the rate of sex-linked recessive lethals in *Drosophila* larvae reared on an irradiated medium, other workers³ have not been able to detect an increase in mutation under similar conditions. However, it has been claimed in recent communications by Parkash^{4,5} that the irradiation of DNA (a component of most foodstuffs) prior to its addition to a *Drosophila* culture medium produces a pronounced increase in mutation in the larvae compared with the unirradiated (and non-mutagenic) DNA sample. This observation, and its relation to the assessment of the hazards involved in the sterilization of food by ionizing radiation, obviously requires an independent verification of this effect.

The present communication describes experiments designed to detect a mutagenic effect of DNA toward *Drosophila* larvae after the DNA had been exposed to a heavy dose of ionizing radiation prior to its addition to a chemically defined and axenic *Drosophila* medium. Although unirradiated DNA is found to be mutagenic under these conditions, the prior irradiation of the DNA does not change the mutagenic effectiveness of the DNA compared with the unirradiated DNA sample.

Irradiation of calf-thymus DNA (British Drug Houses, Ltd.), as a dry powder, was by γ -irradiation (100,000 r.) delivered in a single exposure lasting 6 min 12 sec from a 40,000-c. cobalt-60 source at the Molteno Institute, Cambridge. Both the unirradiated and the irradiated DNA's were added as powders to the chemically defined medium (see Table 1 for the composition) when the temper-

ature of the medium was 55° C. The media were shaken until homogeneous, and dispensed as 25-ml. portions into bottles; cultures which showed signs of microbial contamination over the period of treatment were discarded.

Newly emerged Oregon-K flies were fed for 3 days on a generous supply of yeast, and allowed to lay for 3 h on to a roughened agar surface. The collected eggs were then sterilized using Sang's method⁶, and spread evenly over a sterile agar surface. After incubation at 25° C for 20 h, the newly hatched larvae were transferred under aseptic conditions on to the freshly prepared treatment media, to give a larval density of 100 larvae per 25 ml. of medium. The cultures were then placed at 25° C until the adults emerged.

On emergence, males were individually mated to two virgin Muller-5 females for 3 days for the detection of sex-linked recessive lethal mutations⁷; and, for the detection of autosomal recessive lethal mutations⁷, to females from a stock carrying one second chromosome with the dominant markers, Curly wing and Lobe eye, and the other second chromosome with the dominant marker, Plum eye.

Table 2 illustrates the results obtained when larvae are cultured in a medium containing either 5 per cent unirradiated DNA, or 5 per cent irradiated DNA. Survival was high on each treatment medium, and the developmental rates were essentially the same as the control (no DNA). Both DNA experiments show an increase in the frequency of sex-linked recessive lethal mutation compared with the control (the spontaneous mutation rate of the Oregon-K stock is usually in the range 0.1–0.3 per cent sex-linked recessive lethal mutations). Although DNA appears to be significantly mutagenic under these conditions, there is no significant difference between the irradiated and unirradiated DNA treatments.

Table 3 illustrates the autosomal recessive lethal mutation rates obtained from further experiments, where larvae were cultured on media containing either 5 per cent unirradiated DNA or 5 per cent irradiated DNA. A control (no DNA) is essential when scoring autosomal recessive lethals, since pre-existing lethals may be present in either sex, and care has to be taken not to score them as lethals induced by the treatment. Also, since larval treatments affect early stages of germ cell development (primary spermatocytes, and spermatogonia), tests of allelism between lethals arising from the same male are necessary because of the clonal bunching of mutations from these germ cell stages.

Table 1. COMPOSITION OF THE CHEMICALLY DEFINED *Drosophila* MEDIUM

Compound	Amount (g)
Casein ('Genatosan-low vitamin')	5.00
Fructose	0.75
Cholesterol	0.03
Lecithin	0.04
Agar ('Oxoid No. 3')	3.00
NaHCO ₃	0.14
KH ₂ PO ₄	0.183
Na ₂ HPO ₄	0.189
Aneurine	0.0002
Riboflavin	0.0010
Nicotinic acid	0.0012
Calcium pantothenate	0.0016
Pyridoxine	0.00025
Biotin	0.000016
Folic acid	0.001
Water to 100 ml.	

Table 2. SEX-LINKED RECESSIVE LETHAL MUTATION FREQUENCIES IN *Drosophila* MALES AFTER LARVAL FEEDING TREATMENTS WITH EITHER UNIRRADIATED DNA (5 PER CENT), OR WITH IRRADIATED DNA (5 PER CENT) IN A CHEMICALLY DEFINED AND ASEPTIC MEDIUM

	Control (no DNA)	Unirradiated DNA	Irradiated DNA
Duration of treatment	Entire larval life	Entire larval life	Entire larval life
Survivors (per cent)	98	94	93
No. males examined	46	47	48
Completely sterile <i>F</i> ₁ cultures (per cent)	2	8	4
No. chromosomes examined	440	403	480
No. lethal chromosomes	0	3	3
Lethal frequency (per cent)	0.0	0.7	0.6

Table 3. AUTOSOMAL RECESSIVE LETHAL FREQUENCIES (*F*₁ COMPLETE LETHALS AND *F*₁ LETHAL-MOSAICS) IN *Drosophila* MALES AFTER LARVAL FEEDING TREATMENTS WITH EITHER UNIRRADIATED DNA (5 PER CENT) OR WITH IRRADIATED DNA (5 PER CENT), IN A CHEMICALLY DEFINED AND ASEPTIC MEDIUM

	Control (no DNA)	Unirradiated DNA	Irradiated DNA
Duration of treatment	Entire larval life	Entire larval life	Entire larval life
Survivors (per cent)	97	90	89
No. males examined	46	51	63
Completely sterile <i>F</i> ₁ cultures (per cent)	2	15	13.7
No. chromosomes examined	560	376	644
No. lethal chromosomes	2	4	9
Lethal frequency (per cent) (<i>F</i> ₁ complete lethals)	0.36	1.10	1.40
No. non-lethal <i>F</i> ₁ cultures examined	47 arising from 47 males	42 arising from 42 males	41 arising from 41 males
Average No. of females examined per culture	10	10	10
No. non-lethal <i>F</i> ₁ cultures yielding at least one lethal in the <i>F</i> ₂	2	6	5
Cultures showing mosaicism (per cent) (<i>F</i> ₁ lethal-mosaics)	4.2	14.3	12.1
Total No. <i>F</i> ₂ females examined	490	432	410
No. lethal-bearing <i>F</i> ₂ females	2	6	5
Lethals in <i>F</i> ₂ (per cent)	0.41	1.39	1.22
Total lethal frequency (per cent) (<i>F</i> ₁ complete lethals + <i>F</i> ₁ lethal-mosaics)	4.56	15.40	13.50

Both DNA experiments show a significant increase in *F*₁ complete lethals (detected in the *F*₂ generation) compared with the control, but again there is no significant difference between the mutation rates in the unirradiated and the irradiated DNA experiments. Several bunches of identical (allelic) lethals were detected in the progeny of individual males in both DNA experiments, and each bunch was scored as a single lethal.

The standard autosomal recessive lethal test in these experiments has been extended to an *F*₂ generation by sampling one non-lethal *F*₁ culture arising from each *P*₁ male. This procedure detects those lethals which are not completely established throughout the gonad of the *F*₁ male or female (and detected as *F*₁ complete lethals), but are lethal mutations which occur after a delay, and are established in only a fraction of the gonad of the *F*₁ male or female (*F*₁ lethal-mosaics). The genetical basis of sex-linked recessive lethal-mosaicism is explained in ref. 8; it should be noted, however, that although *F*₁ sex-linked recessive lethal-mosaicism is detected in the *F*₂ generation⁸, *F*₁ autosomal recessive lethal-mosaicism is detected in the *F*₂ generation. Both the irradiated and unirradiated DNA experiments show a significant increase in *F*₁ autosomal recessive lethal-mosaicism compared with the control.

Although the overall autosomal recessive lethal frequencies (*F*₁ complete lethals + *F*₁ lethal-mosaics) for both the unirradiated and irradiated DNA experiments show a significant increase in mutation compared with the control, the mutation rates of the unirradiated DNA and the irradiated DNA experiments are not significantly different from one another.

Unirradiated DNA. The results reported here with unirradiated DNA allow interesting comparisons to be made with the observations of other workers. Thus, Gershenson⁹ has claimed that when *Drosophila* larvae are reared on a medium containing calf-thymus DNA (10 per cent, and later 13 per cent), various types of heritable visible mutations are produced, but no sex-linked recessive lethal mutations. Other workers^{10,11} were also unable to detect an increase in sex-linked recessive lethals after feeding calf-thymus DNA to *Drosophila* larvae, although some phenotypic abnormalities were observed.

Renewed interest in the mutagenic effect of DNA on *Drosophila* larvae arose when it was later claimed¹² that, although DNA does not produce sex-linked recessive mutations, various visible mutations are produced, and these are found to be located on the second chromosome. This observation suggested that DNA, administered by

larval feeding, might have a preferential effect on the second chromosome. This assumption received further general support from experiments in which DNA was injected into adult *Drosophila* males^{13,14}, where it was found to produce autosomal *Minutes*, but no sex-linked recessive lethal mutations.

On the basis of these observations, Mathew¹⁵ has studied the effect of DNA on *Drosophila* larvae reared on a yeast-sugar medium supplemented with 10 per cent (and later with 13 per cent) calf-thymus DNA. In keeping with the findings of previous workers, he found that the sex-chromosome was refractory to the treatment. However, he did observe a pronounced mutagenic effect on the second chromosome, both in the induction of F_1 complete recessive lethals and in F_1 recessive lethal-mosaics¹⁵.

The experiments reported here (Tables 2 and 3) support Mathew's observations that calf-thymus DNA is mutagenic towards the second chromosome of *Drosophila* larvae, in the production of both complete and delayed recessive lethal mutations. However, our experiments show that the sex-chromosome is not refractory to the mutagenic activity of calf-thymus DNA; indeed, it appears to be equally as sensitive as the second chromosome. (Since the second chromosome has approximately twice the genetic material as the sex-chromosome, the spontaneous and induced mutation rates on the second chromosome are expected to show about twice the rate of the sex-chromosome.)

To explain the variance of our DNA-induced sex-linked recessive lethal mutation rates with those of other workers, we might suggest that our more refined culturing technique allows the detection of the slight mutagenic effect which is produced on the sex-chromosome.

Irradiated DNA. Tables 2 and 3 show that the irradiation of calf-thymus DNA, prior to its addition to the larval treatment medium, does not produce a significant increase in mutation over that of the unirradiated DNA. These experiments thus lend no support to Parkash's observations^{4,5} that irradiated DNA produces a significant increase in mutation when fed to *Drosophila melanogaster* larvae.

We thank Prof. J. M. Thoday for supplying the laboratory facilities, and the Pakistan Atomic Energy Commission (A. H. K.), the British Council (A. H. K.) and the British Empire Cancer Campaign for Research (T. A.) for financial support.

Lack of Mutagenic Effect of Irradiated *Drosophila* Medium

THE possibility that irradiated food may be mutagenic gains great importance from the widespread use of radiation for the preservation of food. Stone *et al.*¹ have found increased mutation frequencies in *Staphylococcus aureus* which had been cultured in ultra-violet-treated medium.

More recently, there have been reports²⁻⁵ on cytological abnormalities in plant roots that had been kept in X-rayed culture fluid. Recent experiments on *Drosophila*⁶ have indicated that the incidence of sex-linked recessive lethals and visible mutations may be enhanced by feeding the larvae on irradiated medium. In view of the practical importance of this possibility, a large-scale experiment was carried out to test the genetic effects of irradiated food on *Drosophila melanogaster*.

Bottles with basic medium containing water, glucose, agar, yeast and propionic acid in the proportion of 100 : 10 : 3 : 10 : 0.4 in g were irradiated from a cobalt-60 source at the Atomic Energy Establishment, Trombay, Bombay. Two doses of 150,000 and 300,000 rads were given at a dose rate of 25,000 rads/min. Control bottles were made up in the same way. Treated and control bottles were stocked with 10 young males and 20 virgin females of the wild-type Oregon-K strain. When sufficient eggs had been laid, the parents were discarded. The emerging males, which had undergone their development on irradiated medium, were divided into two groups. In one group, the males were mated with virgin females of genotype $y^{sc}sc$ *In* 49 sc^s ; *bw*; *st* and the progeny was scored for recessive sex-linked lethals and translocations. In the second group, the males were mated with virgin females of an attached-X strain and the progeny was scored for sex-linked visible mutations and large deletions. In both groups, the test was extended over four broods of three days each. Table 1 summarizes the results.

Table 1

Dose (rads)	Sex-linked lethals	Translocations	Sex-linked visibles	Large deletions
0	9/2971 = 0.3%	0/3560	—	—
150,000	10/3532 = 0.25%	0/4031	0/49,056	0/46,871
300,000	8/3766 = 0.21%	0/4160	0/45,300	0/48,014

Clearly, irradiated medium in these experiments had not produced any genetical effects. It is difficult to account for the difference between our results and those obtained by Swaminathan⁶. The strain of males used, the composition of the medium and the radiation dose in our first experiment were the same as in Swaminathan's experiments; in the second experiment, we used an even higher dose of radiation. As regards sex-linked lethals, the difference between our results and those of Swaminathan is only on the borderline of significance for the treated series (χ^2 about 4 for 1 D.F.); the main difference lies in the control rate, which in Swaminathan's experiments was unusually low for the Oregon-K strain. Much more striking is the complete absence of visibles in our experiment as compared with the high frequency of visibles reported by Swaminathan. However, most of Swaminathan's visibles were not tested genetically and may have been phenotypic changes; moreover, it is not clear whether the visible changes in the F_2 of the sex-linked lethal tests occurred in the proportions expected if they had been due to the presence of chromosomes from the irradiated P_1 males. Without further tests, the claim that irradiated medium produces genetic changes of any kind in *Drosophila* does not seem justified.

BIOLOGY

Sexual Dimorphism in *Tilapia*

OBSERVATIONS have shown that the growth rate of males in the *Tilapia* genus is faster than that of the females.

Tilapia aurea (formerly known as *Tilapia nilotica* L.) and *Tilapia galilaea* usually reproduce during the second year of life. Cultivation of *Tilapia aurea* in its second year of life and *Cyprinus carpio* produced low yields of harvestable *Tilapia*, due to the spawning of *Tilapia*.

Mono-sex culture of male *Tilapia aurea* was successful and yielded large fish. Yashouv and Hefetz¹ showed that sex can be differentiated by differences of the openings in the genital papilla. The males have two openings and the females three. Pruginin and Shell² sexed *Tilapia aurea* with a mechanical grader.

Fig. 1. The anal fin in *Tilapia aurea*. Upper, male; lower, female

Fig. 2. The anal and dorsal fins in *Tilapia galilaea*. Upper, male; lower, female

While working with *Tilapia aurea* and *Tilapia galilaea* it was noticed that sexing can be accomplished either according to the genital papilla, or according to the shape of the dorsal and anal fin (Figs. 1, 2).

In males above 60 g the dorsal and anal fins are pointed, while in the females the dorsal and anal fins are rounded and more expanded. In bigger fish these differences are more distinct. These secondary sexual characteristics may be helpful in sexing *Tilapia aurea* and *Tilapia galilaea*.

Presumed Sensory Cells in Fish Epidermis

METHYLENE blue, injected subcutaneously, will stain particular elongated cells, spindle-shaped or flask-shaped, in the epidermis of various teleost fish. Such cells were found by Whitear¹ in the minnow (*Phoxinus laevis*), and afterwards in several other species, both freshwater and marine; that paper should be consulted for references to the scanty earlier literature on the subject. It was suggested that these cells are receptors for the common chemical sense, but as it seems preferable to describe them by a term not indicative of a supposed function, they will be called 'spindle cells' here. For technical reasons, the exact relationship of the spindle cells to the surface of the skin, and to nerve fibres, could not be ascertained by means of the light microscope.

Epidermal spindle cells have now been identified in sections of minnow skin, examined by electron microscopy. Skin from the operculum of *Phoxinus laevis* was fixed in buffered osmium tetroxide, stained in bulk with alcoholic phosphotungstic acid, and embedded in 'Araldite'.

Examination of electronmicrographs has confirmed that the spindle cells do constitute a distinct cell type, which cannot be confused with general epithelial cells, mucous (goblet) cells, or with other secretory cells present in the epidermis. They have been found in sections of skin taken from both inner and outer surfaces of the operculum; methylene blue staining showed them to be present on the chest and gular region. Their distribution is not entirely even, as they tend to occur in groups of three or four, although the spindle cells are not usually contiguous. The adjacent epithelial cells are unmodified, which is one of the characters distinguishing a group of spindle cells from a taste-bud.

Fig. 1 shows the appearance of a spindle cell in *Phoxinus*, as seen in electronmicrographs. The nucleus usually lies at the level of the second or third layer of epidermal cells from the outside, and a neck-like process extends to the surface. Sometimes a pointed process extends inwards also. Usually the outer end of the distal process is slightly bulbous, and it is invariably outlined by a zonula occludens² 0.5–0.75 μ deep. A single microvillus, with no definite internal structure, projects from the spindle cell beyond the level of the skin surface, but it is not clear whether it is always present. Nor is it certain what relationship the microvillus has to the thin cuticle which covers the surface of the skin, but which is easily detached during preparation.

The spindle cells can be recognized in ultra-thin sections, even if the distal process is not included, by the numerous rounded bodies, 0.075–0.1 μ in diameter, which pack the cytoplasm. In phosphotungstic acid stained material, most of these bodies are electron-dense, but some are paler and have the appearance of vesicles. They resemble the inclusions described by Trujillo-Cenóz³ in the sensory cells of fish taste-buds, and their distribution within the cell is also similar. They are most abundant immediately distal to the nucleus, least so proximal to it. Similar bodies do occur in ordinary epithelial cells of the

Fig. 1. Drawing traced from electronmicrographs of three serial sections of a spindle cell in the epidermis on the outer side of the operculum of *Phoxinus laevis*. The cuticle is missing from the surface of the skin

minnow, but not in such numbers as in the spindle cells. The spindle cells often contain a few large electron-dense inclusions, up to 0.5μ in diameter, which, again, may also be found in epithelial cells. Otherwise the cytoplasmic structure of the spindle cells is quite normal. There are a number of elongated mitochondria in the neck region, an endoplasmic reticulum with channels and vesicular profiles, and often some multivesicular bodies. A Golgi complex and a centrosome, not shown in the figure, lie distal to the nucleus. Desmosomes occur between the spindle cell and the adjacent epithelial cells, but they are smaller and scarcer than elsewhere in the epidermis.

In several series of sections, profiles which appear to be of a nerve fibre have been found associated with a spindle cell. One such is shown in Fig. 1, *n*. Here the fibre is indented into the base of the spindle cell. In some cases the apparent nerve fibre lay against the side of the spindle cell or was partially wrapped around the base of its neck. No special synaptic structures have been made out as yet. In some series the nerve fibre appeared to end on, or invaginate into, the spindle cell. In one case a fibre appeared to pass on from one spindle cell to a neighbouring one. It must be admitted that it is not certain that these profiles are of nerve fibres, for epidermal nerve fibres lack many of the structures by which nerves are normally identified, such as sheath cells or prominent neurofilaments. There is a possibility of confusing the profile of a nerve fibre with that of a process from one of the amoeboid cells which are present in the epidermis.

The appearance of some of the spindle cells suggests that they, like the general epithelial cells and the goblet cells,

are deciduous. If they are shed, they are presumably replaced, but how is not clear.

It can now be considered established that the spindle cells do exist in minnow skin. While the function of a cell type cannot be ascertained absolutely from histological studies, the evidence from electron microscopy tends to reinforce, rather than otherwise, the hypothesis that the spindle cells are epithelial sensory cells, and probably chemosensory, for in their fine structure, as well as their general appearance, they resemble the sensory cells of taste-buds. An electron microscope study of the skins of other fishes known to possess spindle cells is in progress.

Taxonomic Investigation of Several *Brassica* Species using Serology and the Separation of Proteins by Electrophoresis on Acrylamide Gels

IN recent years, attention has been drawn to the usefulness of biochemical data in studies of angiosperm taxonomy^{1,2}. Some of these data refer to proteins, and two methods of investigation which have produced interesting results are the serological analysis of plant proteins³ and the separation of proteins on acrylamide gels⁴.

So far as is known, these two methods have not been applied to the same plant material, and the present note is a preliminary account of the application of the methods to the seed proteins of *Brassica nigra* (L.) Koch, *Brassica oleracea* L. and *Brassica campestris* L. On morphological and cytological grounds, these plants are regarded as distinct species, and as a preliminary to an investigation of some disputed aspects of taxonomy within the genus, the two methods of protein analysis have been applied to this well-accepted system.

In the serological section of the work (J. G. V. and A. W.), rabbit antisera to saline extracts of the seeds of the three species were prepared using a series of subcutaneous injections of the seed extract incorporating Freund's adjuvant. Immuno-electrophoretic analyses of the three antisera indicated in all cases a large number of antigen-antibody systems as shown by precipitin arcs. Because of the large number of arcs it was difficult, before absorption, to make an accurate comparison of the three species except in the case of a strong arc formed to a portion of the globulin protein fraction of the seed (Fig. 1, *x*). Against the antisera of all three species, the protein forming this arc in an extract of *B. nigra* was found to migrate towards the negative pole, in contrast to the behaviour of similar proteins in *B. campestris* and *B. oleracea*.

Fig. 1. Immuno-electrophoretic analysis of extracts of: (a) *B. nigra*; (b) *B. oleracea*; (c) *B. campestris* against *B. campestris* antiserum

Fig. 2. Immuno-electrophoretic analysis of *B. campestris* extract against its homologous antiserum. (a) Absorbed with *B. oleracea* extract, (b) absorbed with *B. nigra* extract (*B. campestris* has more proteins different from *B. nigra* than it has from *B. oleracea*)

Fig. 3. Immuno-electrophoretic analysis of *B. oleracea* extract against its homologous antiserum. (c) Absorbed with *B. campestris* extract, (d) absorbed with *B. nigra* extract (*B. oleracea* has more proteins different from *B. nigra* than it has from *B. campestris*)

Fig. 4. Immuno-electrophoretic analysis of *B. nigra* extract against its homologous antiserum. (e) Absorbed with *B. campestris* extract, (f) absorbed with *B. oleracea* extract (*B. nigra* has a similar number of proteins different from both *B. campestris* and *B. oleracea*)

Absorption of the antisera provided a clearer taxonomic comparison (Figs. 2-4). On the basis of the number of antigen-antibody systems, *B. campestris* and *B. oleracea* would appear to be closer to each other than either is to *B. nigra*. This observation was confirmed using the Ouchterlony double diffusion technique.

In the acrylamide section of the work (D. B. and S. W.), seeds were extracted with 5 per cent (w/v) potassium sulphate and the extracts were subjected to electrophoresis by the method of Ornstein and Davis⁵ using the apparatus described by Laycock, Thurman and Boulter⁶. A taxonomic assessment of the three species was based on the appearance and R_f values of the protein bands obtained from the seed extracts (Fig. 5), the results of which could be summarized as follows: (a) four protein bands common to all three species; (b) three protein bands common to *B. oleracea* and *B. campestris* only; (c) two bands common to *B. nigra* and *B. campestris* only; (d) no bands common to

Fig. 5. Diagram of gels of electrophoresed proteins of: (a) *B. oleracea*; (b) *B. campestris*; and (c) *B. nigra*

B. nigra and *B. oleracea* only; (e) one band found in *B. campestris* only; (f) six bands found in *B. oleracea* only; and (g) five bands found in *B. nigra* only.

Both serology and acrylamide-gel separation, based on seed proteins, support the classification of the plants into three taxa. The evidence of these techniques also suggests a closer relationship between *B. campestris* and *B. oleracea* than between either of these species and *B. nigra*. This supports the classification by Schulz⁷ on morphological grounds of the three species into two sections—*Brassicotypus* (*B. campestris* and *B. oleracea*) and *Melanosinapis* (*B. nigra*). Acrylamide-gel separation also provides evidence for *B. nigra* being closer to *B. campestris* than it is to *B. oleracea*.

On the basis of the results obtained, it is felt that serology and acrylamide-gel separation might prove useful in the investigation of *Brassica* taxonomy. In this example, the acrylamide method had the greater resolving power and also has the added advantage that it is a quick and simple technique. It is intended to publish the details of this investigation elsewhere.

We are indebted to the Agricultural Research Council for its support of the serological section of the work.

Seasonal Changes in the Histological Structure of the Spinal Column of *Sorex araneus* (L.)

MORPHOLOGICAL measurements¹ have shown that the spinal column of the shrew (*Sorex*) contracts during the winter and lengthens again in the spring. This lengthening is noticeably greater than the winter contraction. This study shows a relation between these changes and the histological structure of the spinal column.

The material comprised 35 specimens of *Sorex araneus* (L.); 17 were young individuals of the same year's brood, captured in July–October; 11 were wintering animals, captured in January–March, and 7 were wintered adults, 6 of which were captured in May and one in September. Three vertebrae of the lumbar region of the spinal column of each individual were fixed in formol and then decalcified in nitric acid. The preparations were treated by the usual wax embedding method, cut into 10- μ sections, and stained with Lillie's² allochrome method with aldehyde-fuchsin.

Clear seasonal changes were found in the intervertebral disks and in the nucleus pulposus. In young shrews the latter was large and apparently contained much liquid (Fig. 1a), while in the wintering ones it was considerably flattened longitudinally (Fig. 1b), and in the wintered adults again at least as large as in the young ones (Fig. 1c). The annulus fibrosus, surrounding the nucleus pulposus, was without folds in the young specimens; in the wintering ones, particularly those captured late in winter, it was clearly folded at the margins, apparently corresponding to the flattening of the nucleus pulposus. In wintered adults the annulus fibrosus was again unfolded. According to preliminary measurements

Fig. 1. Longitudinal sections through intervertebral disks and nucleus pulposus of (a) a young shrew; (b) a wintering shrew; (c) a post-wintering adult.

the young and the wintering individuals do not show any significant differences in the thickness of the cartilaginous layer situated in the surface of the annulus fibrosus towards the bone pulp. On the contrary, all the wintered adults show vigorous growth in this layer, which therefore is considerably thicker than in the other groups investigated.

The growth of the cartilage begins in the hyaline cartilage bordering the annulus fibrosus (visible as a light layer in Fig. 1b). The substantia compacta at the surface of the hyaline cartilage seems to break and possibly also disappear to some degree when the cartilage grows. The new cartilage is rather loose and weakly PAS-positive, and the cells are hypertrophic. In the wintered shrew captured in the following autumn the cartilage was already strongly PAS-positive, and numerous elastic fibres were found in it and in the annulus fibrosus.

The results presented here show that the contraction of the spinal column of *Sorex araneus* during winter is apparently caused, at least in the main, by the flattening of the nucleus pulposus. As the latter again increases in size in the spring, this flattening in winter cannot be caused by ageing, which, however, also has been found to cause a volume decrease in the nucleus pulposus¹. The vigorous and rapid lengthening of the spinal column in the spring is caused by the volume increase in the nucleus pulposus and by the considerable growth in the cartilage. This growth in the cartilage explains the fact that the spinal column of the wintered specimens is longer than of the specimens before wintering.

Effects of Starvation and Protein Depletion on Mercury Retention in Two Strains of Chickens

Two strains of White Leghorn chickens designated as *R* and *S* have been developed from common parentage at this station¹. When chickens of these two strains were injected intramuscularly with 3 mg mercury as phenylmercuric acetate (PMA) or mercuric chloride/kg/body-wt., 2-4 times more mercury was retained by the livers and kidneys of the *R* strain chickens than was retained by the same organs from the *S* strain chickens^{2,3}. Lillis *et al.*⁴ reported a similar differential retention when chickens from these strains were injected with 9.1 mg copper as cupric acetate/kg/body-wt.

Starvation and/or deprivation of water were selected as possible methods for altering the mercury retention pattern in the organs of these chickens. Feed, water or both were withheld from about forty chickens of the *R* and *S* strains from the time of injection of 3 mg mercury as PMA/kg/body-wt. until decapitation of the chickens 96 h later. The control group received both commercial feed and water *ad lib*. The livers and kidneys of the killed chickens were analysed for mercury^{5,6}.

The effects of deprivation of feed and water on the liver and kidney mercury retention pattern may be seen in Fig. 1. The point represents the mean value of the percentage retention of the injected dose by the livers or kidneys, and the bracket enclosing each point represents the 95 per cent confidence intervals. The values in the livers from the two strains of control chickens were widely separated, indicating statistical significance, as were the values in the kidneys from the two strains. The chickens offered feed only maintained the significant difference in retention. However, the values in the *S* liver and *R* liver overlapped when the chickens were offered water only or neither feed nor water. Thus starvation altered the differences by increasing retention in the *S* strain liver more than the *R* strain liver.

Further diet investigations were predicated on the results of the starvation experiment and on the work of Surtshin⁷ and Surtshin and Yagi⁸. They had demonstrated a change in the renal distribution of mercury following mercuric chloride injections in rats when a sucrose and vitamin diet was substituted for commercial feed.

Approximately 100-day-old *R* and *S* strain chicks were given a commercial feed until 8 weeks of age. The chickens to be depleted were fasted for 24 h and offered, *ad lib.*, granulated sugar and drinking water containing 3.0 ml. of a vitamin preparation, 'ABDEC' drops (Parke, Davis and Co.), per 800 ml. of water*. When the protein-depleted chickens had lost approximately 30 per cent of their body-weight, they were injected intramuscularly with mercuric chloride or PMA at the rate of 3.0 mg mercury/kg/body-wt. The control chickens continued on the commercial ration during the entire experiment and were injected with the mercurials at the same time as the experimental chickens.

Some of the experimental chickens remained on the sugar and vitamin solution diet after injection (unfed chickens (*UF*)), while others were returned to the normal commercial ration (fed chickens (*F*)). At the end of the 96 h all chickens were decapitated and their livers and kidneys excised and analysed.

Fig. 2A graphically illustrates the relationship of the percentage of mercury retained in the liver and kidneys between the *R* strain and *S* strain control chickens, the *R* strain and *S* strain depleted chickens and the *R* strain and *S* strain depleted and repleted chickens after injection with 3.0 mg mercury as PMA/kg/body-wt. The values in the livers and in the kidneys from both lines of the control chickens were widely separated, designating statistical significance. However, in the protein-depleted group, the *R* liver and the *S* liver confidence intervals overlapped, as did the *R* kidney and *S* kidney confidence intervals. Thus, as shown by lack of statistical significance between similar organs from chickens of the two previously different strains, alteration in the retention of mercury by protein depletion

has occurred. Even the percentage retention values of the organs from the protein-depleted *S* chickens were significantly higher than the retention values of similar organs from the *R* control chickens. The confidence limits of the depleted and afterwards repleted chickens again showed a statistical difference. Thus the refeeding with the commercial ration, even for a short time, counteracted to a large degree the change in the retention patterns brought about by the protein-free diet.

The graphic relationship of mercury retention in the organs of the *R* and *S* chickens, depleted and controls, after mercuric chloride injection is illustrated in Fig. 2B. A significant difference may be noted in the mercury retention between the livers and between the kidneys of the *R* and *S* control groups. The mercury retention in the livers of the unfed *R* and *S* chickens, the livers of the fed *R* and *S* chickens and the kidneys of the unfed *R* and *S* chickens were altered by the protein-free diet, so that within each group the significant differences no longer occurred. Only in the case of the *R* and *S* kidney values from the fed chickens did the significant difference remain. The kidneys of the *R* and *S* fed group still continued to show the significant difference in mercury retention. Thus, alteration of the mercury retention patterns of these two strains of chickens, whether injected with PMA or mercuric chloride, may be accomplished by limiting their protein intake.

ANATOMY

Ultrastructure of the Phrenic Nerve

A COMPLETE ultrastructural analysis of the phrenic nerve at a particular level is of interest in view of recent light and electron microscope observations which suggest that there are extensions of subarachnoid space along the length of peripheral nerves¹⁻³. The present observations were made during the course of quantitative investigations on fibres and vessels in the phrenic nerve and on the tissues ensheathing them.

A portion of the left phrenic nerve 5 mm in length was removed from an adult male cat under 'Nembutal' anaesthesia. The specimen was fixed in 2.5 per cent osmium tetroxide buffer, according to the method described by Richardson⁴, dehydrated in acetone and embedded in 'Araldite'. Complete transverse sections were cut with a glass knife on an L.K.B. microtome and mounted over a 750- μ aperture in a copper grid coated with lead hydroxide after Karnowsky⁵ and examined in a Siemens 'Elmiskop F' electron microscope. The image of the entire cross-section of the nerve was photographed

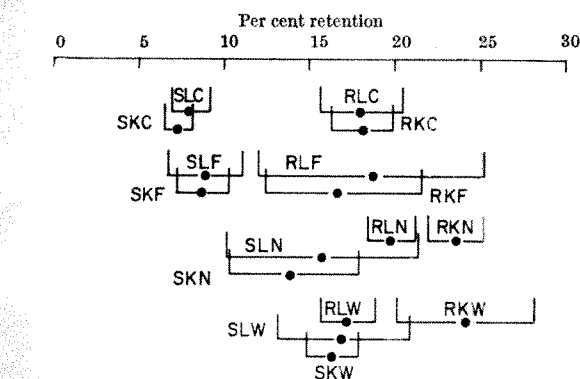

Fig. 1. Effect of the lack of feed, water or both on the percentage of mercury in the livers and kidneys of two strains of chickens 96 h after injection with 3.0 mg mercury as phenylmercuric acetate per kg body-weight. Brackets indicate 95 per cent confidence-levels. *R* and *S*, Strains of chickens; *L*, liver; *K*, kidney; *C*, control chickens; *F*, feed only; *W*, water only; and *N*, no feed or water

Fig. 2. Brackets indicate 95 per cent confidence-levels. *R* and *S*, Strains of chickens; *L*, liver; *K*, kidney; *C*, control chickens; *F*, protein-depleted and -repleted chickens; *UF*, protein-depleted chickens

Fig. 1. Transverse section of phrenic nerve from a cat (original montage: $c. \times 4,500$). Scale = 100μ

and a montage constructed, the total magnification being 4,500 (Fig. 1).

At the level examined, 4 nerve fasciculi were present of which the two larger ones comprised 3 and 6 subfasciculi respectively. The sheaths surrounding the fasciculi and subfasciculi are referred to here as the perineurium. In all, 802 myelinated fibres, ranging from 4 to 20μ in external diameter, and 2,094 unmyelinated fibres were

Fig. 2. Transverse section of part of the perineurium showing alternate layers of fibroblasts and collagen fibres ($c. \times 42,000$). Scale = 1μ

present with an apparently random distribution of the myelinated fibres throughout the section. The unmyelinated fibres were aggregated in groups within the fasciculi; the groups in peripheral regions of the fasciculi contained more unmyelinated fibres (50–200) than those nearer the centre (5–20). Each group of unmyelinated fibres was associated with a small number of myelinated fibres ranging from 0.5 to 2μ in external diameter.

Surprisingly few blood or lymphatic vessels were seen throughout the section and they were all less than 10μ in diameter. A total of 23 such vessels was found within the fasciculi and a further 5 were situated in the extra-fascicular connective tissue immediately adjacent to the perineurium. Unlike the observations made by Shanthaveerappa and his colleagues, no extensions of 'perineurial epithelium' enveloping intrafascicular vessels were seen.

Alternating layers of cells and intercellular 'spaces' containing numerous collagen fibres formed the basis of the perineurial layers (Fig. 2). The cells were identified as fibroblasts because of their

close proximity to collagen fibres, some of which lay in invaginations of the cell membrane—a relationship which has also been found in other situations (Porter and Pappas⁶; Wessel⁷).

The possibility that the cells of the perineurium, identified here as fibroblasts, correspond to those lining the subarachnoid space was investigated in cats. The results obtained indicate that the meningeocytes of both the pia mater and arachnoid in the region of spinal nerve roots generally form a limiting membrane to the subarachnoid space and are only rarely separated from it by tissue containing collagen fibres.

The present observations, therefore, do not support the view that there are extensions of the subarachnoid space along peripheral nerves.

Electron Microscopic Observations on the Carotid Body

ELECTRON microscopic investigations of the carotid body¹⁻⁶ have provided some basic information concerning the cell types present and the characteristics of nerve fibres and blood vessels. Since the early work of De Castro^{7,8}, the glomus cells have been widely assumed to be the chemoreceptor component of the carotid body. Lever, Lewis and Boyd⁵ found that nerve fibres containing a concentration of mitochondria and microvesicles terminated near glomus cells. Ross⁴, on the other hand, found that the few terminal axons in apposition with glomus cells did not contain mitochondria or synaptic vesicles. In neither investigation was specialization of opposing cell membranes observed. In the examination of the carotid body recorded here, further characteristics of both the nerve endings on the glomus cells and vascular endothelium have been determined.

Cats were anaesthetized with sodium pentobarbitone (30 mg/kg) intraperitoneally. The trachea was cannulated

and the larynx and pharynx reflected. The carotid body was perfused for 1–2 min via the common carotid artery with 5 per cent glutaraldehyde in Sorensen's phosphate buffer at pH 7.3–7.4. The carotid body was then removed, cut into small blocks and fixed for 5 h in glutaraldehyde. The tissue was washed in phosphate buffer for 45 min, post-fixed in osmium tetroxide for 16 h, dehydrated in ethanol and embedded in araldite. Ultra-thin sections were cut on an L.K.B. microtome, stained with lead and uranyl acetate and examined in a Siemens 'Elmiskop I' electron microscope.

Nerve endings were frequently seen and occurred in intimate relationship with cells containing osmiophilic granules. These cells have been variously referred to as glomus cells by Lever, Lewis and Boyd⁵, chemoreceptor cells by Ross⁴ and Type 1 cells by De Kock^{6,9}. The nerve endings have been identified by their content of mitochondria and vesicles, the latter with a diameter of approximately 500 Å. At times two nerve endings abutted directly on an individual cell. The plasma membranes of the axon and the glomus cell were separated by a distance of 85–170 Å. Along opposing cell surfaces, specialized electron-dense zones (0.2–0.5 µ in length) were found, usually more than one at each axon–glomus junction. At these specialized sites, the plasma membranes were a further 50–100 Å apart and the intervening cleft was of increased density, though the distinct lamination that occurs in desmosomes was not observed (Fig. 1). Cytoplasmic densities, which sometimes appeared to be fibrillary, occurred in the adjoining cytoplasm and extended up to 500 Å into the glomus cell and axon. These electron-dense structures were observed only between the nerve endings and glomus cells, and in several electron micrographs vesicles within nerve endings were concentrated at these sites. No comparable concentration of osmiophile granules or other vesicles was seen in the glomus cell. Many nerve endings contained dense particles approximately 150 Å in diameter. Mostly these occurred in clusters having an overall diameter of up to 500 Å. Though there was some intermingling with synaptic

vesicles, the particles were often segregated in areas of cytoplasm of diminished density and encircled by mitochondria. These particles may be similar to the 'solid' particles described by Gray¹⁰ and Taxi¹¹. In addition, within the nerve endings, there was an occasional vesicle (up to 0.1 µ in diameter) with a central electron-dense core similar to those described in other nerve endings^{10,11}.

Blood vessels were numerous and sinusoidal, and in cross-section were always lined by at least three endothelial cells. The walls of some vessels were thin and occasional pericytes were seen; others were composed of one or two layers of muscle fibres, but none contained elastic tissue. As well as the usual cytoplasmic constituents, two additional features were observed in the endothelial cells. Fenestrations (500–700 Å in diameter) occurred in attenuated segments of endothelial cells in thin-walled blood vessels. These have not previously been observed in the carotid body. Secondly, dense-walled or coated vesicles and caveolae were found in the endothelium. These specialized micropinocytotic vesicles are believed to be concerned with protein uptake^{12–14}. Though they have been reported in frog endothelium, this appears to be the first time their presence has been recorded in mammalian endothelium. They were also seen in glomus and supporting (satellite or Type 2) cells.

The specialization at the axon–glomus cell junction described in this investigation bears a close resemblance to the synaptic contacts which are known to occur in the central nervous system and believed to be sites of chemical transmission^{10,11,15–17}. The nerve endings in the carotid body could have a similar function. For many years it has been considered probable that chemical transmission is concerned in the generation of nerve impulses in the carotid body (see Heymans and Neil¹⁸ and Anichkov and Belen'kii¹⁹ for reviews of this problem), and recently Eyzaguirre, Koyano and Taylor²⁰ have presented evidence that an acetylcholine-like substance may be involved in this process. However, we have not seen vesicles of any sort accumulating on the glomus cell side of the dense areas of intercellular contact, and only occasionally on the axon side—a feature of synapses where chemical transmission is believed to occur. Furthermore, there is no evidence that the nerve endings described here are related to chemoreceptor afferent fibres in the sinus nerve.

MICROBIOLOGY

Timing of Protein Synthesis during Germination and Outgrowth of Spores of *Bacillus cereus* Strain T

THE emergence of a vegetative cell from a dormant bacterial spore represents one of the most direct examples of intracellular differentiation. During this transition, progressive changes in the pattern of RNA synthesis¹, classes of ribosomal particles², metabolic activity^{3,4} and structures^{5,6} are observed. Although the complete differentiation process is dependent on RNA and protein synthesis, not all the individual stages depend on new protein synthesis. It has been generally assumed that this transition involves two stages: (a) germination, which is characterized by degradative reactions and breaking of the dormant state, and (b) outgrowth, which is dependent on biosynthesis of new cellular components. The metabolic activity observed after the addition of germinating agents is probably due to a combination of two responses: activation or 'unmasking' of some dormant enzyme system and/or early biosynthesis. It is the purpose of the present report to determine whether these two stages are separated in time and to determine whether transcription and translation are ordered events during outgrowth.

Examination of the nature of increases in an essential system for energy, such as glucose oxidation, provides a useful model for distinguishing between the phenomena of activation during germination and biosynthesis during outgrowth. To distinguish between the two processes, the effect of inhibitors of protein synthesis on outgrowth was examined. Spores of *Bacillus cereus* strain T were heat-activated at 65° C for 2 h, centrifuged, and washed, and germination was initiated as described in Table 1. After 10 min, the germinated spores were centrifuged, resuspended in *tris*-phosphate buffer and the effects of actinomycin D, chloramphenicol and puromycin on amino-acid incorporation and initial rates of glucose oxidation were examined (Table 1). Leucine incorporation during outgrowth was inhibited by more than 93 per cent by inhibitors of protein synthesis, whereas these agents had no effect on the activity of the glucose oxidizing system.

If the protein synthesizing system during outgrowth is dependent on new mRNA synthesis, then one would expect that the half life of amino-acid incorporation in the presence of actinomycin D would be of the same order (a few minutes) as that observed in vegetative cells⁷. To test this possibility, heat-activated spores were germinated (see Table 1) in the presence of ¹⁴C-L-leucine. At intervals, 20 µg/ml. of actinomycin D was added, and the incorporation of radioactivity into protein was followed. As shown in Fig. 1A, addition of actinomycin D with the germinating agents completely blocks leucine incorporation, lending further support to the view that dormant spores are devoid of stable mRNA (ref. 8). Five minutes after the addition of germinating agents, protein synthesis is initiated. The rate of leucine incorporation rises gradually for the next 30 min. When actinomycin D was added 10 or 19 min after the onset of germination, leucine incorporation continued in each case for 3 min and then ceased. The apparent half-life of protein synthesizing ability (1.5 min) is in agreement with the

Table 1. EFFECT OF INHIBITORS OF PROTEIN SYNTHESIS ON AMINO-ACID INCORPORATION AND GLUCOSE OXIDATION BY GERMINATED SPORES

Incubation conditions	Leucine incorporation µmoles/mg spores	Q _{O₂} µl O ₂ /mg spores/h
Control	0.39	28.2
Actinomycin D (20 µg/ml.)	0.020	27.3
Chloramphenicol (40 µg/ml.)	0.012	28.8
Puromycin (40 µg/ml.)	0.028	25.7

Spores were germinated at 30° C in 0.04 M *tris* buffer, pH 8.3, containing 10⁻³ M KH₂PO₄, 0.5 mg adenosine/ml., 2.5 mg L-alanine/ml. and 0.5 per cent glucose. Outgrowth conditions: 1 mg spores/ml. in *tris*-phosphate buffer containing 0.5 per cent glucose, 30° C. Radioactive leucine (1 µg/µg/ml.) incorporation was followed for 40 min. The respiratory activity (Q_{O₂}) was the initial rate of glucose oxidation.

Fig. 1. A suspension of spores (1 mg/ml.) was heat-activated at 65° C for 2 h, centrifuged, washed and resuspended in the synthetic medium of Nakada¹¹. Germination was initiated by the addition of 0.5 mg adenosine/ml., 2.5 mg L-alanine/ml. and 0.5 per cent glucose at 30° C. (A) 2-¹⁴C-L-leucine (1 µg/µg/ml.) was added at time zero to each flask. Actinomycin D (20 µg/ml.) was added at 0, 10 and 19 min as indicated. Incorporation of radioactivity was followed in the hot TCA-insoluble fraction. (B) Respiratory activity was followed during germination by measuring the rate of O₂ uptake in the presence or absence of 30 µg/ml. of actinomycin D or 40 µg/ml. chloramphenicol. The glucose oxidation by dormant spores is included as a control. (C) Enzyme synthesis during germination. At intervals, aliquots were removed into pre-chilled buffer containing 100 µg/ml. chloramphenicol to stop further enzyme synthesis. The cells were washed, disrupted and assayed for alkaline phosphatase (P) or α-glucosidase (M) in the presence of chloramphenicol as described elsewhere (ref. 8). In a control flask, α-glucosidase activity was followed in a culture germinated in the presence of 100 µg/ml. chloramphenicol. The units of enzyme activity for P and M are 0.05 µmoles and 0.1 µmoles substrate hydrolysed/h respectively.

half-life of pulse labelled RNA (2 min) during outgrowth^{8,9}. These and other data¹⁰ support the conclusion that during outgrowth protein synthesis is dependent on transcription.

The increase in the respiratory activity during germination and outgrowth is shown in Fig. 1B. This increase is biphasic. The first appearance of respiratory activity coincides with the initial decrease in optical density accompanying germination (Fig. 1C) and reaches a plateau at the time (10 min) when germination is complete. Five minutes later, a second rise in respiratory activity occurs which continues for 11 min and leads to a 50 per cent increase in the rate of glucose oxidation. Chloramphenicol (CM) and actinomycin D inhibit the second rise but have no effect on the initial rise in respiratory activity. Therefore, germination leads to an activation of respiratory enzymes, and this is followed during outgrowth by the synthesis of components of this system.

Comparison of Figs. 1A and 1B suggests that following germination the entire genome may not be available for transcription. Synthesis of components of the respiratory system is initiated 10 min after the onset of protein synthesis and lasts for only a brief period. Furthermore, ordered transcription during outgrowth is evidenced by following two enzymes synthesized during outgrowth (Fig. 1C). Both α-glucosidase and alkaline phosphatase

are synthesized in steps, and each step occupies only a small fraction of the time required for the first signs of cell division (220 min). Analysis of acrylamide-gel electrophoretic patterns of cell extracts at various times during outgrowth showed that different classes of proteins were synthesized at each time interval⁸. Similarly, sequential synthesis of three enzymes during synchronous division of vegetative cells following outgrowth has been observed⁸.

Two conclusions are apparent from these observations. First, the conversion of a dormant spore to a vegetative cell involves two distinct stages, germination and outgrowth. Germination does not involve protein synthesis but leads to an activation of enzymes in the spore, whereas outgrowth is ordered. During this period mRNA has a half-life of a few minutes. Therefore, the sequential synthesis of proteins must reflect differences in the time of transcription of corresponding portions of the genome.

VIROLOGY

Nucleic Acid of Infectious Laryngotracheitis Virus

THERE is now considerable evidence that halogenated derivatives of the nucleoside 2'-deoxyuridine inhibit the growth of viruses that have DNA as their nucleic acid constituent but not of those containing RNA^{1,2}. Inhibition occurs at a stage of nucleotide assembly and the thymidine analogue 5-iodo-2'-deoxyuridine (IUdR) has been shown to be incorporated into the DNA of vaccinia virus³. For cells infected with herpes simplex, this inhibition is partly reversible when thymidine is added together with the drug⁴.

Close similarities in the structure and development of the virus particles of infectious laryngotracheitis (ILT) and those of the herpes group of viruses were noted in a previous report⁵. A more recent study⁶ has demonstrated marked similarities in the ether sensitivity and fine structure of these particles and in the type of cytopathic effect produced when they are propagated in cultured chicken embryo kidney (CEK) cells. While these observations suggest a close resemblance between members of the herpes virus group and ILT virus, they are not sufficient to allow chemical similarities to be presumed. In an effort, therefore, to obtain information as to the type of nucleic acid which is present in ILT virus, experiments were performed to determine the effects of IUdR on the growth of ILT and herpes simplex virus (HS) in CEK monolayer cultures.

Fig. 1. Plaques produced in CEK monolayers by (a) ILT and (b) HS

A plaque system previously described for ILT⁷ was used for the assay of both viruses. Modifications to this method included the use of a growth medium described elsewhere⁸ for chicken fibroblasts and 6-cm plastic Petri dishes specially coated for use in cell culture (Falcon Plastics, Baltimore Biological Coy., Md., U.S.A.). The cultures were stained with neutral red diluted 1:10,000 in phosphate buffered saline (PBS), 5 days after inoculation with ILT, and 7 days after inoculation with HS. Plaques were counted the day after the addition of stain. The morphology of plaques produced by both viruses was similar, but those due to ILT appeared sooner. Plaques produced by both types of virus are shown in Fig. 1.

In the growth experiments the HFEM strain of HS was used and was obtained as yolk-sac propagated material from Mr. I. Jack of the Royal Children's Hospital, Melbourne. It was passaged twice through CEK and gave a titre of 1.57×10^7 plaque-forming units (P.F.U.) per ml. A lyophilized preparation of the Queensland strain of ILT was used, an egg-propagated strain of moderate virulence with a plaque titre of approximately 10^6 P.F.U. per ml.

Cell monolayers, washed with PBS, were inoculated with 1.0-ml. amounts of each virus and allowed to adsorb for 1 h at 37° C, in a humidified incubator gassed with 5 per cent CO₂. Unadsorbed virus was then removed by rinsing 3 times with PBS. Five ml. of a maintenance medium, which differed from the growth medium in that it contained only 2 per cent calf serum, was added. Concentrations of IUdR of 0, 10, 100, or 1,000 γ /ml. were included in the medium, the latter concentration being the threshold of toxicity for established monolayers of other cells⁹. All cultures were then returned to the incubator.

Whole cultures containing each drug-level were collected 24, 48 or 72 h after infection. Cells were removed from the culture dish with a rubber 'policeman' and, after pipetting several times, the cell clumps were treated for 1 min by a Mullard ultrasonic generator—a procedure found to break up cells effectively and to release more virus than could be obtained by freezing and thawing. Cultures containing no drug were treated in a similar fashion immediately after

Fig. 2. The growth curves of ILT and HS in CEK monolayers in the presence of varying concentrations of IUdR

adsorption and washing, to provide an estimate of the 'background' level of virus associated with cells during the eclipse phase of the growth cycle. All samples were snap frozen and stored at dry ice-box temperatures until assays could be carried out.

Results of one experiment are shown in Fig. 2. This indicates that considerable inhibition of both viruses occurred at all concentrations of the analogue studied. The recovery of HS at higher drug concentrations after treatment for 24 h may have been due to the survival of IUdR resistant mutants⁹ of HS and their subsequent replication in later cycles of growth.

The inhibition of both viruses by IUdR, when grown under identical conditions, indicates that the nucleic acid of ILT is DNA, and provides further evidence for the inclusion of this virus within the herpes virus group.

Note added in proof. Since this letter was submitted for publication, evidence has come to hand that some halogenated derivatives of 2'-deoxyuridine, notably 5-bromo-2'-deoxyuridine, inhibit the multiplication of certain RNA viruses which require the participation of DNA at an early stage of multiplication (Bader, *Virology*, **22**, 462; 1964; Thormar, *ibid.*, **26**, 36; 1965). However, in conjunction with other reports of similarities between ILT and HS, a virus known to contain DNA, the parallel inhibition of both viruses by IUdR must be regarded as further evidence that the nucleic acid of ILT is DNA.

SOIL SCIENCE

Measurement of Exchangeable Aluminium in Acid Soils

MANY acid soils are known to contain exchangeable aluminium, but no satisfactory quantitative method for its determination has hitherto been available. This has proved to be a handicap in investigations of the degree of saturation with metal cations, suspected toxicity of adsorbed aluminium to crop plants as well as other soil properties influenced by exchangeable aluminium.

Neutral solutions of various salts will displace a definite amount of aluminium under standard experimental conditions. The quantity of aluminium released in this way may exceed the cation exchange capacity of the soil, so that some way must be found for distinguishing between the exchangeable and non-exchangeable components present in the extract. A technique for estimating this latter function is proposed here.

Exchangeable aluminium is displaced with difficulty by other cations, but it can be effectively removed by a long series of successive extractions. If it is assumed that the amount of non-exchangeable aluminium dissolved during each extraction in the series is constant, then the sum of the contributions from this source can be subtracted from the total extractable aluminium to give an estimate of exchangeable aluminium. For this approach to be successful, experimental conditions with respect to soil-to-solution ratio, temperature and period of contact must be kept constant during extraction.

In accordance with a Nernst type distribution, it may be expected that with each successive extraction, a steadily decreasing amount of exchangeable aluminium

Fig. 1. Characteristic curve for the progressive extraction of aluminium from acid soils

will be released together with a constant quantity of non-exchangeable aluminium. The Nernst curve should thus become linear if continued beyond the point at which all exchangeable aluminium has been removed.

In Fig. 1, the curve *AB* represents the progressive removal of both forms of aluminium and the linear part *BC* that of non-exchangeable aluminium only. The amount of the latter removed per extraction will determine the slope of *BC* which will also depend largely on the solubility of the solid phase aluminium compounds. When *BC* is extrapolated, *AD* will represent exchangeable and *DE* non-exchangeable aluminium.

The experimental procedure is as follows. Place 5 g air-dry soil in a tared 100-ml. centrifuge tube and add 50 ml. extracting solution adjusted to the field pH of the soil; shake for exactly 2 min in a reciprocating shaker. Centrifuge and decant the clear supernatant into a suitable container. Re-weigh the tube so as to obtain the weight of the occluded solution; add a further 50 ml. of extractant, shake, centrifuge and decant. This procedure is repeated 24 times, decanting into a separate container each time. Determine the aluminium present in each extract and plot the cumulative data as shown in Fig. 1.

Exchangeable aluminium measured by this technique appears to be a characteristic of the particular soil and is reasonably constant irrespective of the nature of the extractant as shown in Table 1.

Table 1. EXCHANGEABLE AND NON-EXCHANGEABLE ALUMINIUM EXTRACTED BY DIFFERENT SALT SOLUTIONS

Solution	Aluminium removed (m.equiv. per cent)		
	Total aluminium	Non-exchangeable aluminium*	Exchangeable aluminium
0.2 N KCl	5.7	0.075	3.9
0.2 N NH ₄ Cl	6.0	0.079	4.0
0.2 N CaCl ₂	5.4	0.074	3.6
0.2 N NH ₄ NO ₃	6.0	0.087	3.8
N NaCl	6.1	0.090	3.8

* Per extraction.

Aluminium was determined by the method of Frink and Peech¹.

The sample used was from the *A*₁ horizon of a highly weathered acid ferrallitic soil with a pH value of 4.5 in water and 3.8 in N potassium chloride. It has a cation exchange capacity of 6.0 m.equiv. per cent with a base saturation of 20 per cent (excluding aluminium). The five extracting solutions were all adjusted to pH 4.0, which was regarded as the field pH value of the soil. Twenty-four separate aluminium determinations are required for each estimate of exchangeable aluminium, so that differences between the five extractants could be due to experimental error. Exchangeable hydrogen probably accounts for the difference between cation exchange capacity and total bases including exchangeable aluminium.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, November 15

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 10.30 a.m. and 2.30 p.m.—Colloquium on "Phase Measurement Throughout the Spectrum".

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Dr. D. E. Stevenson: "The Assessment of Possible Health Hazards Associated with the Use of Pesticides".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. Ralph Audy (U.S.A.): "Red Mites and Typhus. V. Old and New Horizons".*

INSTITUTION OF MECHANICAL ENGINEERS, MANUFACTURE AND MANAGEMENT GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Engineer and the Law".

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. Collin Cherry: "The Nature of Human Communication". (First of three Cantor Lectures on "World Communication").

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at the College of Further Education, Hatfield Road, St. Albans), at 7.30 p.m.—Dr. J. S. Gourlay and Dr. C. K. Warren: "The Chemist's Contribution to the Building Industry of the Future".

Tuesday, November 16

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 1.30 p.m.—Mr. E. F. Schumacher: "A Map of Knowledge: Seeing Where Everything Belongs".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Mr. P. A. Scott: "Port of Tema".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 12, House of Commons, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Scientific Aspects of Food Additives", opened by Prof. R. A. Morton, F.R.S., Prof. A. C. Frazer, C.B.E., and Dr. L. Golberz.

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. F. J. C. Roe: "Factors Involved in Lung Cancer Causation". (Sixth of Fifteen Lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

INSTITUTION OF MECHANICAL ENGINEERS, PROCESS ENGINEERING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Application of Non-Destructive Testing to Process Plant Inspection".

Wednesday, November 17

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 2 p.m.—Prof. I. H. Mills: "The Relationship of Adrenal Androgen to Cortisol Secretion".*

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. David Oates: "Tell Al Rimah—The Temple and Ziggurat".

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. E. J. Williamson and Mr. J. T. Houghton: "Radiometric Measurements of Emission from Stratospheric Water"; Mr. A. W. Brewer and Mr. A. W. Wilson: "The Measurement of Solar Ultraviolet Radiation in the Stratosphere"; Mr. D. O. Staley: "Radiative Cooling in the Vicinity of Inversions and the Tropopause".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, RADAR GROUP (at 9 Bedford Square, London, W.C.1), at 5.30 p.m.—Dr. P. G. F. Caton: "The Use of Doppler Radar in Meteorological Research".

WORTHFUL SOCIETY OF APOTHECARIES OF LONDON, FACULTY OF THE HISTORY OF MEDICINE AND PHARMACY (at Black Friars Lane, Queen Victoria Street, London, E.C.4), at 5.30 p.m.—Dr. T. D. Whittet: "The Apothecaries in the Great Plague of London, 1665" (Sydenham Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 6 p.m.—Prof. Erwin Meyer: "Electroacoustics".

INSTITUTION OF MECHANICAL ENGINEERS, INTERNAL COMBUSTION ENGINES GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. F. J. Wallace and Mr. E. J. Wright: "Characteristics of a Two-Stroke Opposed-Piston Compression-Ignition Engine Operating at High Pressure".

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College, Exhibition Road, London, S.W.7), at 6 p.m.—Mr. R. Blanchflower: "Damping Properties of Engineering and Viscoelastic Materials".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 6 p.m.—Prof. Leon Festinger (Stanford): "The Role of Efference in Visual Perception". (Further lectures on November 18 and 19.)*

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (at the Angel Hotel, 109 High Road, Ilford), at 7.30 p.m.—Dr. H. G. Rains: "The Chemistry of Paint Formulation".

Thursday, November 18

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (joint meeting with the British Society for Parasitology, at Manson House, 26 Portland Place, London, W.1), at 2.30 p.m.—Symposium on "The Pathology of Parasitic Diseases". 7.30 p.m.—Laboratory Meeting at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1.

OPERATIONAL RESEARCH SOCIETY (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 4.30 p.m.—Mr. H. Boothroyd and Mr. M. F. Shutter: "Beyond Stock Control".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. T. C. Askwith, Mr. A. Cameron, Mr. R. F. Crouch and Mr. R. Gohar: "The Surface Chemistry of Hydrodynamic Lubrication of Point Contacts".

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. A. A. T. Finn: "Tailing Dam Construction at Mufuhura Copper Mines, Ltd., Zambia"; Mr. J. Pereira and Mr. C. J. Dixon: "Evolutionary Trends in Ore Deposition".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Annual General Meeting. Prof. A. G. Walker: "Harmonic Spaces in Differential Geometry" (Presidential Address).

INSTITUTE OF PETROLEUM, INFORMATION DISCUSSION GROUP (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Mr. Leslie Wilson: "Information for the Technologist: Prospects for Improved Services".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. H. S. Wolff: "Problems of Advanced Technology in Medicine". (Seventh of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)*

INSTITUTE OF REFRIGERATION (at Lloyd's Register of Shipping, 71 Fenchurch Street, London, E.C.3), at 6 p.m.—Informal Discussion on "The Refrigeration Industry and the Metric System".

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. G. E. Bessey: "Current Developments Affecting the Design and Use of Mortars for Building Purposes".

Friday, November 19

INSTITUTE OF NAVIGATION (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1), at 5.30 p.m.—Mr. T. G. Thorne: "Multi-purpose Airborne Radar".

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Instrument Scale Graduator" opened by Mr. L. B. S. Golds.

ROYAL INSTITUTE (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. J. M. Bruckshaw: "The Channel Tunnel".

Friday, November 19—Saturday, November 20

ZOOLOGICAL SOCIETY OF LONDON; MAMMAL SOCIETY OF THE BRITISH ISLES; and ASSOCIATION FOR THE STUDY OF ANIMAL BEHAVIOUR (in the Meeting Room of the Zoological Society of London, Regent's Park, London, N.W.1), at 10.30 a.m. daily—Symposium on "Play, Exploration and Territory in Mammals".

Saturday, November 20

INNER LONDON EDUCATION AUTHORITY (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. R. D. MacCuaig: "Modern Methods of Locust Control".*

Monday, November 22

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Major N. J. D. Prescott, R.E.: "The Geodetic Satellite—SECOR".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. H. Braunsteiner (Innsbruck): "Clinical Significance of Triglyceride Determinations, Especially in Relation to Age, Body Weight, Different Forms of Diabetes and Thyroid Disease".*

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Prof. Collin Cherry: "The Communication Explosion". (Second of three Cantor Lectures on "World Communication").

SOCIETY FOR VISITING SCIENTISTS (at The English-Speaking Union, Dartmouth House, 37 Charles Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "The Retrieval of Scientific Information". Chairman: Dr. H. T. Hookway. Speakers: Prof. E. Kaiser, Dr. W. Batten and Mr. A. St. Johnston.

Monday, November 22—Tuesday, November 23

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2)—Conference on "U.H.F. Television".

Monday, November 22—Friday, November 26

INSTITUTE OF METALS (at the Royal Commonwealth Society, Craven Street, London, W.C.2)—Third International Conference on "Plutonium".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER or ASSISTANT LECTURER IN STATISTICS IN THE EDUCATION DEPARTMENT, to be concerned with research with the work of advanced students and with teaching—Prof. B. A. Peel, Department of Education, The University of Birmingham, Birmingham 15 (November 17).

LECTURER (with a research bias and a physics/electronics background) IN THE DEPARTMENT OF ELECTRICAL AND CONTROL ENGINEERING—The Secretary, Battersea College of Technology, Battersea Park Road, London, S.W.11 (November 19).

LECTURERS or ASSISTANT LECTURERS IN MATHEMATICS in the School of Mathematics and Physics—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 88C (November 20).

READERS, SENIOR LECTURERS, LECTURERS or ASSISTANT LECTURERS IN PHYSICS in the School of Mathematics and Physics—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 88C (November 20).

DEMONSTRATOR (preferably honours graduate in agriculture or agricultural botany) IN AGRICULTURE (Crop Agronomy)—The Registrar, University of Nottingham, Nottingham (November 22).

RESEARCH ASSISTANT (preferably with a veterinary degree) IN VETERINARY MICROBIOLOGY, to join a group working on the pathogenesis of enteric infections—The Registrar, The University, Liverpool, 3, quoting Ref. CV/328/N (November 22).

CHAIR IN STATISTICS—The Secretary, Royal College of Advanced Technology, Salford 5, Lancashire (November 25).

LECTURER or ASSISTANT LECTURER IN GEOGRAPHY, with particular reference to physical geography—The Assistant Secretary, London School of

Economics and Political Science, Houghton Street, Aldwych, London, W.C.2 (November 25).

CHAIR OF PHYSIOLOGY—The Secretary of the University Court, University of Glasgow, Glasgow (November 26).

LECTURER IN ANALYTICAL OR PHYSICAL CHEMISTRY—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (November 26).

EXPERIMENTAL OFFICER (interested in the design and construction of equipment for a wide range of psychological experiments, and preferably with a knowledge of electronics) IN THE DEPARTMENT OF PSYCHOLOGY—The Registrar, The University, Manchester, 13, quoting Ref. 195/65 (November 30).

LECTURER (Grade II) IN MATHEMATICS (Pure or Applied)—The Registrar, University Senate House, Bristol, 2 (November 30).

READER AND LECTURERS (2) IN ANATOMY; and a LECTURER (with a degree in pharmacology, physiology or pharmacy) IN PHARMACOLOGY at Makerere University College, Uganda (University of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (November 30).

READER (preferably, but not necessarily, qualified in a branch of classical applied mathematics) IN APPLIED MATHEMATICS—The Secretary, Battersea College of Technology, Battersea Park Road, London, S.W.11 (November 30).

LECTURER (Grade II) (preferably with special interests in one of the following fields: invertebrate functional morphology, respiratory physiology or fish physiology) IN ZOOLOGY—The Registrar, University Senate House, Tyndall Avenue, Bristol, 2 (December 1).

SENIOR LECTURER IN VETERINARY MEDICINE (small animals)—The Secretary, The Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (December 1).

CHAIR OF MATHEMATICS at the London School of Economics and Political Science—The Academic Registrar, University of London, Senate House, London, W.C.1 (December 2).

SENIOR LECTURERS, LECTURERS and ASSISTANT LECTURERS IN THE DEPARTMENT OF STATISTICS—The Secretary, University of Edinburgh, Edinburgh (December 10).

LECTURER (suitably qualified graduate with special qualifications in educational foundations (history and theory) or in educational sociology) IN EDUCATION at the University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, December 15).

SENIOR TECHNOLOGICAL OR TECHNOLOGICAL (with experience in museum work and photography, in addition to histopathology) IN PATHOLOGY in the Faculty of Veterinary Science—The Registrar, University of Khartoum, P.O. Box 321, Khartoum, Sudan (December 22).

VISITING PROFESSOR IN VETERINARY PATHOLOGY—The Registrar, University of Khartoum, P.O. Box 321, Khartoum, Sudan (December 22).

CHAIR OF AGRONOMY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Australia, December 31.)

CHAIR OF LOGIC AND METAPHYSICS—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife, Scotland (December 31.)

CHAIR OF PHARMACEUTICS at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, December 31.)

CHAIR OF SOCIOLOGY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, December 31.)

CHAIR OF VETERINARY ANATOMY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Australia, December 31.)

SECOND CHAIR OF BIOLOGY—The Secretary, University of Lancaster, Bailrigg House, Lancaster (December 31.)

FISHERIES OFFICER (national of the United Kingdom or the Republic of Ireland, with a good science degree and experience of fisheries management, including marketing and processing) IN MALAWI, to collect statistics and develop and demonstrate to local fishermen improved methods of fishing appropriate to local conditions—The Appointments Officer, Ministry of Overseas Development, Room 301, Eland House, Stag Place, London, S.W.1, quoting Ref. RC.289/134/01.

HEAD OF THE DEPARTMENT OF MATHEMATICS (Grade IV)—The Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N.7.

LECTURER OR ASSISTANT LECTURER (well-qualified physicist and preferably with experience of the application of physics in industry) IN PHYSICS—The Registrar, Bradford Institute of Technology, Bradford, 7.

LECTURER (well qualified in physics and preferably experience in some branch of electronics) IN THE DEPARTMENT OF PHYSICS—Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N.7.

MICROBIOLOGISTS—Dr H. B. Noel, Chairman, Department of Biology, University of Waterloo, Ontario, Canada.

PROFESSOR OF STATISTICS AND OPERATIONAL RESEARCH—The Registrar, Bradford Institute of Technology, Bradford, 7.

PROFESSOR IN PHYSICAL CHEMISTRY—Prof Harry E. Gunning, Head, Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada.

RESEARCH ASSISTANT (qualified in chemical engineering, physics, chemistry or other related discipline) IN THE DEPARTMENT OF CHEMICAL ENGINEERING, to work on a Ministry of Technology research contract investigating the liquid-liquid extraction of metal ions—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 37/2/AF.

RESEARCH TECHNICIAN (with qualifications, not necessarily a degree, or experience in microbiology, biochemistry or chemistry) IN THE DEPARTMENT OF BIOCHEMISTRY for work in bacterial enzymology—The Registrar, The University, Liverpool, 3, quoting Ref. 329/N.

TECHNICAL ASSISTANT (preferably with some experience in radioactive counting techniques) to work with a whole-body radioactivity counter used in clinical research—The Secretary, Department of Radiotherapeutics, Addenbrooke's Hospital, Cambridge.

NEW grating SP200G infrared spectrophotometer

high resolution

Unicam now offers all the advantages of a grating filter monochromator combined with the proved features of the SP200 prism spectrophotometer. The first order of the NPL grating is isolated by four interference filters, brought into play by an automatic mechanism exclusive to Unicam. The resolution is as high as 3 cm^{-1} at 3000 cm^{-1} and stray light is less than 1% throughout most of the range and never exceeds 2%. The wavenumber accuracy is better than 2 cm^{-1} at 1000 cm^{-1} and 4 cm^{-1} at 3000 cm^{-1} . To this performance are added the advantages of the flat bed recorder, the accessible sample compartment and the convenient operation of the SP200. The new SP200G is constructed and finished to the high degree of precision for which Unicam instruments are famous. Descriptive literature is available on request.

The

Histokinette

stays on the job

**Histokinette
special features
include:—**

- Up to 24 hours delayed start
- Double processing capacity
- One or more motor members and baskets
- Unbreakable tissue basket and containers

Diagnostic reports to hand hours earlier than they would be with manual processing and in far greater numbers—the release of a valuable technician for other duties... these are the outstanding advantages of the Histokinette Automatic Tissue Processing machine. Once the Histokinette has been put into operation, it will *without supervision* go through the entire cycle of fixation, dehydration, impregnation in wax, or alternatively can be set up for the washing or staining of tissues. It can handle large numbers of specimens at the same time and while staff is off duty—speed up almost any technique by ensuring quicker and more thorough penetration by reagents.

A 24-hour clock is fitted as standard. Change over to 1 hour or 7 day cycles (the latter of great value in double embedding and bone decalcification techniques) is simple and rapid.

TOWARDS A UNIVERSITY OF THE AIR

IN the last of nine papers presented to Section L (Education) of the British Association for the Advancement of Science at its meeting in 1964, Dr. K. Adam discussed the responsibility of television: this responsibility has since been sharpened by the continuing discussions on the feasibility and the scope for a 'university of the air'. To that suggestion, indeed, Dr. Adam made passing reference, though he had reservations on the ground of costs. In his closing remarks he insisted that, however well such a development went, broadcasting, in the face of the imperious needs of education, was an aid to teaching and not a substitute for it, an ancillary and not a principal, a satellite but not a saviour. In this paper he was content to urge that television research was an essential part of the joint responsibility of the provider and the community he serves. It needed to be enlarged and given depth and we should no longer be asked to accept facile and unsupported opinions.

Beyond this, Dr. Adam suggested that the unique quality of television transmission was the transmission of experience. News was no longer 'then' but 'now'. Here, he thought, lay the special responsibility of broadcasting, and particularly of television. Among the most important services which television could undertake, he suggested, were those that could be rendered to the emergent and developing countries and in the field of science. Not only, in this way, could such services extend our comprehension of a dramatically changing world, but also they could show man himself, in the person of the scientist, as a growing creature, whose birthright is progress, and who, whether his subject is crystallography or cosmology, is a human being under the weight of his invention and his experiment. This kind of comprehension or reassurance in a world which is always more of man's making, and less the work of Nature, contributes directly to the permanent education which we need to keep us in a state of balance and of wonder.

If, therefore, this is the unique contribution of television, and one which it does supremely well because it is uniquely qualified for the purpose, we should be careful that other demands are not allowed to deflect it from such a function. It follows that this is a joint responsibility of the producer and of the community. It was thus strange to find that in a series of twelve articles on "The B.B.C.'s Duty to Society", published in *The Listener* during June–September 1965 (to which Dr. Adam himself contributed), almost no reference was made to this aspect. Indeed, only Baroness Barbara Wootton appeared to refer to the way in which broadcasting and television could contribute to spreading awareness of the social revolution of our time. She went on, in fact, to comment that broadcasting programmes gave her no sense of the march of science as the great intellectual adventure of our time. Neither these programmes nor the earlier contributions to the series of Sir Hugh Greene or Dr. Adam appeared to her to convey any sense of the universality of the process by which cumulative additions to knowledge are made, or of the unique opportunity of broadcasting to equip ordinary people with the mental tools, and to help them to form the mental beliefs appropriate to the age in which they live.

Such a suggestion is contradictory to Sir Hugh's affirmation that the British Broadcasting Corporation has

a duty to take account of the changes in society and to be ahead of public opinion rather than always to wait on it, and even against his admission that, at least in the secular and scientific fields, to-day's heresies often prove to be to-morrow's dogmas. That, however, was his only reference to science, which was not even mentioned by Dr. Adam—though he reiterated the point about news being 'now' which he made in his earlier paper. Furthermore, an editorial comment in *The Listener* on September 2 covering the whole series seems to indicate that the Corporation has missed the whole point of Baroness Wootton's criticism or even of Dr. Adam's address to the British Association.

In the light of all this we may now turn to consider the proposal for a university of the air, of which the Prime Minister said at Guildhall, London, in September, that, although much work remained to be done, the Government had gone a long way towards working out the educational functions and content. A high-powered educational advisory committee had reached agreement on an outline plan and had recommended that the university should offer primary courses leading to degrees and cover professional, technical and refresher courses. He was satisfied that the educational problems could be overcome, but admitted that there were big technical and financial problems. He hoped that discussions with the broadcasting authorities would start in the near future. Use of a fourth channel, perhaps on a shared or partnership basis, was not excluded.

In this context, research interest attaches to the statement, "University of the Air", issued in June by the University of Strathclyde. This discusses some aspects of the structure and organization of a national university of the air: arguments in favour of the establishment of such a university are regarded as overwhelming. Our normal educational resources are already so over-strained as to be incapable of fostering a dynamic and flexible method of educating and re-educating adults as well as children to fit new roles in a rapidly changing society. However, it would be unrealistic to suggest that these urgent and growing demands should be met by the British Broadcasting Corporation or the Independent Television Authority. Their output is different in essence and intent from that envisaged from a university of the air. While it can be argued that the 'University of the Air' should be independent also of existing academic institutions to give it the desired freedom to experiment, it would, for the time being, be wise to limit the new organization to a selected group of existing educational institutions. Such an arrangement would enable it to draw from them the co-operation and support necessary to further its experiments and validate their results.

It is suggested, accordingly, that, as a practical step, the Government should delegate responsibility for local development of the University of the Air to regional boards, on which would be represented educational interests sympathetic to the idea. The work of the regional boards would be co-ordinated under a United Kingdom Educational Television Authority. This Authority would also be responsible for establishing a national library of filmed programmes, and for gradually taking over the construction and maintenance of transmitter

stations. The production studios should remain in the control of regional boards and educational institutions. A structure of this kind should permit the advantages of centralization in cutting certain overheads in ensuring a common purpose, as well as those of decentralization in ensuring the maximum utilization of regional resources in teaching skills and technical facilities. Production of programme courses should be spread over those institutions best able to deal with particular subjects. It would be necessary for each regional board to undertake the preparation and dissemination of preparatory courses which would lead students to uniform entrance standards for the degree courses provided by the University of the Air.

The statement from the University of Strathclyde rejects as undesirable and uneconomic any attempt at 100 per cent coverage by broadcast television. This would be an inefficient exploitation of the four broadcast channels likely to be available for educational television. As the service provided by a University of the Air would attract at any time only a very small (although important) fraction of the whole population, it is suggested that it would be better to devise a means of reaching all parts of the country by a combination of methods, confining broadcast television to those areas and to those purposes for which it is best fitted. Accordingly, it is proposed that only the major conurbations, containing 60–70 per cent of the population, should be covered by broadcast television, using a small number of low-power transmitters, and serving the rest of the country by distributed film prints or programmes which could be projected in schools or halls or homes. This would make it possible to conserve the channels now available in the very-high-frequency band to the point where four or more channels could be made available at each transmitter station for simultaneous broadcasting.

Acceptance of 60–70 per cent coverage in this way does not mean that the public beyond the range of television and sound transmission would be unable to enrol at the University of the Air. It is proposed that all the programmes provided for television by the University should be recorded and prints of the original transmission can readily be circulated anywhere for viewing as already indicated. All the courses would be supported by carefully prepared lecture notes and reading lists, and each week all enrolled students would be required to submit exercises for marking and comment by tutors. Whereas in areas of sparse population, broadcasting becomes more expensive than supplying film prints, apart from the additional disadvantage of the inefficient use of broadcasting channels which are scarce, in areas of dense population the cost per student of providing film prints for group or individual viewing would far exceed that of reaching the students by broadcasting television. Experience gained at the University of Strathclyde suggests that total production costs of the 16-mm films would be about £100 per hour in the universities, as compared with £5,000 per hour quoted for the British Broadcasting Corporation's studios. Preliminary surveys carried out on behalf of the University of Strathclyde have already confirmed that local transmitters in Band IV with omnidirectional aerials sited at the centres of large cities and towns would only require low power of the order of 1 kW, or 4 kW of effective radiated power. The cost of such a transmitter is estimated at about £30,000.

This statement is obviously more optimistic than is Mr. B. Jackson, director of the National Extension College

in Cambridge—the experimental teaching unit set up in 1963 to pilot the concept of a University of the Air. Work began with 'Dawn University'—a series of first-year lectures from Cambridge broadcast before breakfast and limited to television teaching. This and later experience, such as the six-week television experiment called College of the Air on Anglia Television, lead Mr. Jackson to suggest, first, that the University of the Air should be designed as a research-based project at least for the next three years. Next, he suggests that considerable caution is desirable as to the audience or students to be attracted, quite apart from the question of numbers. Furthermore, his experience seems to indicate that the crucial element in a University of the Air would be correspondence tuition, and although he thinks a fourth channel might help, he does not regard it as ideal. It would be preferable to have the equivalent spread over rural radio and television channels, and he suggests that, looking at the problem from a primarily educational point of view, there are strong reasons for avoiding the confines of a separate television channel.

Mr. Jackson's caution does not necessarily invalidate the Strathclyde view, which fully recognizes the importance of further enquiry and that the steps recommended would only be experimental. It should be noted, however, that Mr. Jackson is insisting, above all, that decisions should be concerned with students and not simply with techniques. His caution is tinged with a realism which is distrustful of political idealism which does not rest firmly on ascertained facts and is merely wishful thinking. Some of those facts, moreover, lie outside the field of the Authority responsible for programmes for any such University of the Air. This is evident from a preliminary memorandum on "Broadcast Adult Education and Public Libraries"—the implication of which the Library Association has accepted.

This memorandum by Mr. J. F. W. Bryon points out that students enrolling for such courses will need access to a wide range of literature for which they will look largely to the public library. For that reason alone, liaison is desirable between those planning the courses and librarians, so that the implications for the provision of books may be taken into account from the earliest stages. So far as numbers of potential users are concerned, Mr. Bryon suggests it might help if enrolment forms were distributed and collected by public libraries. The memorandum also notes that the public library might frequently offer a convenient centre for viewing. It is, however, in regard to the content of reading lists that consultation between lecturers and librarians is particularly desirable, but it is not forgotten that many students may require instruction or guidance in the use of a library.

What emerges from all three contributions is the grave danger of allowing any project for a University of the Air to become the plaything of party politicians. The resources required are far too large for Britain to engage in any idealistic project which is not closely related to demands which have definitely been ascertained and for which adequate resources can be committed. This is an inescapable responsibility of Governments, but a responsibility nevertheless rests alike on the broadcasting and the educational authorities, including the universities, to see that assets and resources are not wasted and that programmes are directed to practical and realizable objectives. This is the responsibility of producer and community to which Dr. Adam referred.

CITATION INDEXING

Science Citation Index 1964 Annual Cumulation

An International Interdisciplinary Index to the Literature of Science and Technology in Eight Parts. Part 1: Citation Index, A-Duke, Cols. 1-3168, Part 2: Citation Index, Duke-Kofe, Cols. 3169-6584, Part 3: Citation Index, Koff-Roes, Cols. 6585-10000, Part 4: Citation Index, Roes-Zzeb and Anonymous, Cols. 10001-13518, Part 5: Citation Index, Patent Citation Index and Acknowledgements, Cols. 13519-16404, Part 6: Source Index, Anonymous and A-Geye, Cols. 1-2658, Part 7: Source Index, Geye-Ogre, Cols. 2659-5316, Part 8: Source Index, Ogre-Zz, Cols. 5317-7893. Editor: E. Garfield. (Philadelphia: Institute for Scientific Information, Inc., 1965.) 1,250 dollars.

THE *Science Citation Index* for 1961 was reviewed in *Nature*, 203, 446 (1964), when an account was given of the technique for using a citation index. The *Index* for 1964 is an improvement in many ways. It was published on a quarterly basis during the year, and the volumes reviewed here represent the annual cumulation. Whereas the *Index* for 1961 appeared as the result of a research grant from the National Science Foundation and the National Institutes of Health, the present index can be considered as the first to be issued on a production basis, and it is obviously an advantage that the publication delay has been reduced.

The other major change has been the inclusion of a list of all the citing papers. This greatly improves the convenience of using the *Index*, since, as is inevitable in this type of index, many of the citing papers will prove to be quite irrelevant for the subject of the search. With the earlier *Index*, this point could only be established by checking the actual journal; now, by referring to the list of citing papers, from the titles one can correctly reject many of the non-relevant papers. The physical price to be paid for this is that the number of volumes has increased from five to eight; the financial price is that the cost has risen to 1,250 dollars. Against this, there has been an increased coverage; the source journals have increased only to 700 from 613, but the separate journal papers have risen from 102,000 to 151,000. In addition, for the first time, patents are included, and the 47,000 patents issued in the United States in 1964 bring the total of source items up to 199,000. It is a disappointment to find that the standard computer print-face, severely reduced in size, is still being used, and also that the *Index* is still heavily biased towards the life sciences. It is to be hoped that the balance will be redressed in the *Index* for 1965, when, it is stated, more than 1,000 journals will be covered.

The present value and future potentialities of the *Science Citation Index* are difficult to assess. The cost is such that it can be considered prohibitive for individuals, yet for a library it would represent only a fraction of the cost of one human indexer. The usefulness of the *Index* would be greater if its coverage were wider, yet this would result in an increase in cost unless there was a corresponding increase in the number of purchasers. Before placing a subscription, a librarian needs to be reasonably satisfied that the citation index is not only a useful tool, but also that it will not cease publication within a year or so, for it is only when the library shelves have a run covering at least five years that the majority of users of the library will be prepared to accept it as a method of retrieving information. Only then will it be possible to assess how usefully it can fulfil its basic purpose and find whether its obvious technical weaknesses are obviated by the flexibility and ease of compilation. The use of a computer for this purpose makes possible a number of interesting alternatives. Already an Automatic Subject Citation Alert (ASCA) service is being offered, by which subscribers can obtain regularly citations to papers by selected authors. There is no reason why cumulations covering selected

subject fields should not be issued at a price which would appear more reasonable to prospective purchasers. There are also, of course, known ways of improving the operational performance of a citation index; some of these, by increasing the complexity, would raise the cost, but improvement in the citing habits of authors would do more than anything else to increase the usefulness of a citation index. Perhaps the time is coming when editors of scientific journals should take the same active steps to obtain a high quality of citing as many have recently been doing for abstracts and titles. C. W. CLEVERDON

COMMUNICATION, THE SOCIAL WEB

Communication Processes

Edited by Frank A. Geldard. (NATO Conference Series, Vol. 4.) Pp. x+293. (London and New York: Pergamon Press, 1965.) 100s. net.

COMMUNICATION Processes is Volume 4 of the NATO Conference Series of volumes, being the *Proceedings* of a symposium held in Washington in 1963, under the sponsorship of the NATO Advisory Group on Human Factors. This military sponsorship should not mislead one, however, because the contents will be of interest to a wide civil readership and, indeed, have, on the whole, no limitation to military situations at all, but relate to many kinds of formal social institution.

The book is divided into five principal sections: (1) data presentation; (2) data transmission; (3) language barriers and language training; (4) group communication; (5) man-computer communication. Each consists of an introductory paper with very extensive attendant discussions. About one-fifth of the whole contents is written in French. The conference was concerned essentially with human factors of communication and not at all with electronics or engineering; of course, human factors are themselves very important to engineers. The participants may be regarded as being the most prominent psychologists and sociologists concerned with communication processes—an impressive galaxy of stars from the various NATO countries, representing a wide range of interests and opinions.

At least a third of this book is devoted to 'pragmatic' aspects of communication; that is, to the importance of personal prejudices, to people's positions in a social hierarchy, to their cultural backgrounds and to non-cognitive factors of language; the subtle connotations of language, one's image of oneself and other determinants of human communication. This aspect of the book is valuable, for such vital matters are not always evident to those engaged in the development of technical means of communication, and they are ignored by those who take a strictly logical view of semantics, a view which seems so prevalent to-day. A 'yes' can be turned to a 'no' by a smile, or by one's knowledge of the speaker's reputation. Meanings are not properties of words but are relationships, between words and people, in various situations and conditions. These pragmatic factors can be of particular importance in cross-cultural communication, already hampered by the strict untranslatability of languages. However, John Blæk, of Ohio State University, plays down these factors, in his paper "Language Barriers and Language Training", and quotes several historical examples of people, drawn from different cultures, nevertheless getting on together quite well; Columbus, for example, among the natives, and Marco Polo. But his examples are very special ones and, besides, the fact that such people were not promptly murdered does not mean that they were understood correctly. I cannot help quoting the old story of Captain Cook who, when he asked a native "What's that silly-looking animal called?", was given the answer: "Eangaroo", which means in Aborigine "I don't know" (so I am told!). Of course, the 'word

barrier', in this context, is itself open to misinterpretation. Languages are not barriers in the sense of 'walls', but rather in the sense of 'ambiguous signposting'. But Prof. Black is a professor of speech and is concerned with such things as morphemes, syntax and phonemes, rather than with the *rapprochement* between two human beings engaged in discussion. Other discussants, especially psychologists, emphasized the conceptual difficulties involved in translation, without in any way denying the value of Prof. Black's experimental work.

In his opening paper at the fourth session on "Group Communication", M. Didier Anzieu also brings out the importance of these language 'barriers' in various social groups. Such barriers can be strong between people, or groups, of the same nominal language, by reason of personal status in a group hierarchy, or by personal non-explicit connotations of words and phrases. (How important is language to the maintenance of class divisions in Britain!) Lack of feed-back in an organization means one-way communication (orders, directives) and can lead to hostility. Our social behaviour and attitudes in a group depend not only on 'message received' but also on our unconscious adjustments based on assumptions about other people's social behaviour in like circumstances. Behaviour is not absolute but relative. There may also be conflict between the needs of the individual and the needs of the group.

Other papers presented dealt with more strictly stimulus/response, mechanistic, aspects of communication and control, relating especially to man-computer systems. It is interesting, however, to hear psychologists' views of such 'formal' aspects which are more commonly discussed by engineers. Questions of human 'matching' to machines were considered, signal codings, sensing, identifying and interpreting. The papers, though presented against a military background, contain much of quite general interest to other situations to-day: in industry, for example. As said earlier, this military emphasis seems a little unfortunate.

COLIN CHERRY

SOIL SCIENCE

Experimental Pedology

Proceedings of the Eleventh Easter School in Agricultural Science, University of Nottingham, 1964. Edited by E. G. Hallsworth and D. V. Crawford. Pp. xi+414. (London: Butterworths Scientific Publishers, 1965.) 85s.

Forty years ago the word 'pedology' was being used somewhat tentatively in Great Britain, where the examination of soils had, in the main, been an application of the analytical skills of chemists. Indeed, in the middle of last century Thompson and Way had discovered the property of cation exchange; but their results were inexplicable until the laws of mass action and the properties of colloidal particles were established. Then followed a revival of interest in the subject, and by the 1920s the theory of cation exchange seemed to offer a simple explanation of the natural development of soil acidity and the ability of the soil to release nutrients for the plant.

Meantime, the pedologists in Europe and North America had been accumulating observations in the field on profile characteristics. They had tended to rely heavily on geology, at least in the preliminary stages of soil classification, and it was obvious that both physical and biological sciences were required to provide explanations for the mobility of ions and colloidal material responsible for horizon differentiation, for the attack on litter by micro-organisms and small animals in search of energy, and for the modification of the soil by the products of decomposition and deposition.

Responses in biological activity to fluctuations in habitat, resulting from moisture and temperature changes

and the redistribution of components, inevitably increase the complexity of a soil system. However, the precision of recently developed analytical techniques has stimulated the study of slow biochemical reactions, and rapid progress has been made in all the sciences applied to soil. Communications within and between the various disciplines have also been assisted since 1927 by congresses and commission meetings of the International Society of Soil Science and by numerous national and regional conferences.

The 1964 Easter School at the University of Nottingham was an opportunity of reviewing the present position with respect to the experimental approach to pedology, and the *Proceedings* comprise 29 papers. They fall into five sections, dealing with: (1) geochemistry and weathering of soil minerals; (2) redistribution of inorganic substances; (3) biological aspects of soil formation; (4) pedo-genetic studies; (5) demonstrations. The discussions of groups of the papers are most informative in revealing differences of opinion and promising lines of further investigation.

The nature of the surfaces of fine particles is discussed by J. J. Fripiat and the organic geochemistry of sedimentary rocks by W. D. Evans. J. Rausell-Colom *et al.* describe detailed studies on the weathering of mica, by X-ray diffraction and spectrographic analysis and by electron probe, while R. M. S. Perrin has assessed the rate of weathering from the composition of drainage waters. In two papers, S. Hénin and G. Pedro, and S. Caillère and S. Hénin, examine the sub-division and dissolution of rocks by weathering speeded up in the laboratory by Soxhlet extraction, and the formation of clay minerals by the chemical treatment of specific minerals, the transition being followed by thermal loss-of-weight curves. J. van Schuylenborgh discusses the mechanism of the formation of sesquioxides and the cementing agents in different horizons, while D. Acquaye and J. Tinsley deal with the solubility of silica and its movement through soils under various conditions. The mobility of phosphate, as observed in radioautographs of crumbs previously immersed in carrier-free $H_3^{32}PO_4$ solution, is described by D. Gunary *et al.*, and D. H. Yaalon deals with the distribution of anions under arid conditions, and C. B. Wells with the deposition of calcium carbonate.

In the biological group of papers, G. V. Jacks reviews ideas on the 'organic' weathering of solid rock by bacteria, fungi and algae at the start of soil formation. J. D. Ovington deals with the accumulation of nutrients in woodlands, D. S. Jenkinson with the decomposition of carbon-labelled ryegrass, R. Bétrémieux and S. Hénin with the products of fermentation in profile development, and N. A. Burges with the various micro-organisms involved in the attack on plant tissues. The effects of animal activity on the litter and on soil structure are described respectively by J. van der Drest and G. W. Heath, while C. Jeanson and G. Monnier discuss the influence of soil fauna on the stabilization of structure. From the numerous experimental data presented, it is clear that much remains to be done to clarify the effects of the numerous factors met with in the field and the interdependence of the various groups of organisms involved.

In section 4, C. Bloomfield reviews the present position of theories on the mechanism of podsolization, D. V. Crawford presents evidence of the complex interaction of physical, chemical and biological processes which cannot be examined in isolation, while H. P. Blume and E. Schlichting emphasize that the basic problem is, in fact, to sort out the various soil-forming processes. V. B. Proudfoot deals with the mutual benefits to archaeologist and pedologist from the examination of prehistoric sites, D. G. McKinlay gives a detailed account of the physics of fluvial transport and deposition, and T. W. Walker advances analytical data in support of phosphorus as a key element in pedogenesis because of its role in the

ecological sequence. How far the various aspects of weathering, transport and deposition are related to soil classification is discussed by E. G. Hallsworth in a scheme based on leaching sequence and conforming with the conclusions reached by experimental pedology.

Three short papers on demonstrations of pyrochromatography, watertable studies, and the effect of stones on soil transport, conclude the volume, which has author and subject indexes, has been most carefully edited and very well produced.

A. M. SMITH

MANUFACTURE OF WOOD PULP

Pulping Processes

By Dr. Sven A. Rydholm. Pp. ix+1269. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, Inc., 1965.) 285s.

THE author of *Pulping Processes* is a Swede and, judged by the introduction, a disciple of the late Erik Hagglund, professor of cellulose technology and wood chemistry at the Royal University of Technology, Stockholm. He has spent his career of some 20 years in the Swedish pulp industry, principally on industrial research, and is at present assistant research director of one of the foremost Swedish pulp and paper mills. In this volume he has produced one of the most comprehensive books on pulping processes yet available, and it is written in faultless English. Indeed, the work may be described as almost monumental, and it will undoubtedly serve as a standard reference work on wood pulping for many years to come.

The book commences with a survey of the forests of the world and includes and discusses data on wood species, the gross and minute structures of trees and woody fibres, and the chemical composition and reactions of their components. The operations involved in the preparation of cellulose pulp from the forest to the finished product are then described and discussed. The section headings comprise the manufacture of unbleached pulp and of bleached pulp, including the preparation of the chemicals required. A final chapter surveys the properties and uses of pulp and the world pulp industry. The treatment of the subject is such that the physical and chemical processes involved are emphasized, rather than the purely technological aspects. In this way the influences of process variables on the yields and properties of pulps are demonstrated and analysed. The chemical reactions involved, the preparation and recovery of pulping chemicals, and the manufacture of organic by-products are also dealt with.

It is inevitable that even a book having such a high standard of attainment should also have its weak points, if only because its wide and detailed scope places a considerable strain on the expert knowledge of a single individual. The introduction suggests that one of these limitations is apparent to the author, namely, the fact that the time involved in writing such a book means inevitably that some of it is soon out of date. This applies with particular force to the statistical data and the author's discussion of the pulping industry of the world, which are based on 1960 figures and facts; a great deal of importance has happened in this connexion in the past 5 years. A further, and perhaps more important, limitation arises from the fact that, to the author, pulp means almost exclusively wood pulp and there is scant and not always wholly accurate treatment of fibrous pulping materials other than wood. Quantitatively and on a world-wide basis, such pulps may be of relatively small significance at the present time as compared with wood pulp. However, to developing countries they are often the only source of available paper-making material, and as time goes on they will certainly increase in importance; they certainly deserve more than 16 pages in a book of this size.

It should be emphasized that the foregoing criticisms should be viewed in their correct perspective, especially as the latter refers only to non-woody fibres. So far as wood pulping processes are concerned the book can be recommended highly and without reserve.

JULIUS GRANT

SEMICONDUCTOR CONTROLLED RECTIFIERS

Semiconductor Controlled Rectifiers

Principles and Applications of *p-n-p-n* Devices. By F. E. Gentry, F. W. Gutzwiller, N. Holonyak, jun., and E. E. Von Zastrow. (Series in Solid State Physical Electronics.) Pp. xv+383. (Englewood Cliffs, N.J., and London: Prentice-Hall International, 1964.) 120s.

DURING the ten years following its discovery in 1949, the transistor developed, at least in principle, to the point where it could replace 'hard' thermionic valves in all but three fields, namely, for generating high powers at radio frequencies, in electrometer applications, and in micro-wave applications. The field effect transistor now permits replacement of the valve in electrometers, and various so-called 'solid state klystrons' now becoming available are rapidly encroaching on the micro-wave field. However, the eclipse of 'hard' valves by the transistor is as nothing compared with the rapidity and thoroughness with which the thyristor, or semiconductor controlled rectifier, has swept the 'soft' valve into history. The only field left now for the thyatron (and its various relatives) is a very tenuous grasp on applications in which working voltages are too high for present-day semiconductor devices. Indeed, thyristors now also seriously threaten the survival of the magnetic amplifier, which clings to a place in contemporary technology only by virtue of economic factors and industrial inertia, both of which are likely to be only of transient significance.

Needless to say, the rapid coming to maturity of thyristor technology has led to the production of a spate of books expounding the essentials both of device design and circuit application. *Semiconductor Controlled Rectifiers* is a good example. It is well produced, thorough in its treatment, extensive and reliable. In that it describes recent and relatively sophisticated developments, it is a second-generation book—no pioneering text, but likely to be useful for a considerable period. The emphasis is clearly forward application, rather than device design, although the latter is covered sufficiently well to give an adequate introduction, and certainly should make it relatively easy to understand why available devices have the properties that they have.

However, two criticisms must be made. First, one-sixth of the book is taken up with a summary of the elementary theory of semiconductors and the *p-n* junction. This is really inexcusable. Many good text-books on this subject are now available and, in any event, the fundamentals are a necessary part of the education of every electrical engineer to-day. To me it seems quite possible that it was only included because of the present fashion in the United States and elsewhere not to write or publish short books. The present volume is not a particular sinner in this respect, but certainly could have been reduced in length by at least one-third without loss. Secondly, circuit technique using thyristors is expounded in a 'cookery book' fashion. This is still customary in electronics text-books. The outstanding systematic exposition of the technique of circuit design is still awaited for reasons which are not clear. Perhaps the subject has lacked the intellectual cachet necessary to attract attention of a sufficiently serious kind. For whatever reason, electronic circuit design has yet to find its Mendeleev, and can scarcely be considered a science in

the sense, say, of the definition used by Prof. P. B. Medawar in a recent article (*Encounter*, August 1965). To sum up, the book is thorough, reliable, and with a wide range of proven circuit arrangements described in adequate detail; sufficient, in fact, to enable the engineer to develop the skill necessary for the design of new configurations.

W. FISHWICK

ALKALINE EARTH METALS

Handbuch der Experimentellen Pharmakologie
Begründet von A. Heffter. Fortgeführt von W. Heubner.
Erganzungswerk. Herausgegeben von O. Eichler und A. Farah. Band 17: Ions Alcalino-Terreux. Teil 1: Systèmes Isolés. Sous-Editeur: Zénon-Marcel Bacq. Pp. xx+574. 148 D.M. Teil 2: Organismes Entiers. Pp. xviii+1068. 198 D.M. (Berlin: Springer-Verlag, 1963, 1964.)

IN these two volumes the editors have brought together twenty Belgian authors who have, between them, contributed seventeen chapters. The first volume deals with the action of the alkaline earth metals studied in isolated preparations, the second with work on whole organisms.

Z.-M. Bacq opens the first volume with an interesting account of the importance of the alkaline earth metals in living matter. In the second chapter, the chemistry and physical chemistry of magnesium, calcium, strontium and barium are discussed by E. Fredericq. The next four chapters deal with the action of the alkaline earths on simple enzymes (L. Massart and R. Vercauteren), blood coagulation (Y. Bounameaux and J. Lecomte), complex enzyme systems (C. Liébecq) and micro-organisms (Z.-M. Bacq). The intra- and extra-cellular distributions of Ca and Mg are discussed by E. Schoffiels. This is followed by chapters dealing with the action of alkaline earth metals on tissues of invertebrates (Z. M. Bacq), on nerve fibres and nerve cells (J. A. Cerf and I. Leusen), on neuromuscular transmission (J. E. Desmedt), on skeletal (X. Aubert), cardiac (J. G. Henrotte) and smooth muscle (Z.-M. Bacq and R. Charlier) and blood elements (J. Lecomte and Y. Bounameaux). The first volume ends with a most useful review by E. Schoffiels and Z.-M. Bacq on the factors which control the states of equilibrium of the various cations.

The second volume concentrates on the many metabolic processes in which the alkaline earth metals are involved in the whole organism. The first two chapters are written by M. J. Dallemagne and deal in great detail with calcium in the circulation, bones and teeth. The third chapter is devoted to the cerebrospinal fluid and the central nervous system (I. Leusen) and to the aqueous humour (Z.-M. Bacq). Subsequent chapters deal with problems concerning the kidney (G. Barac), milk (G. Peeters and R. Vercauteren), sweat (Z.-M. Bacq), gastrointestinal secretions (H. Brabant and J. van Geertruyden), blood vessels and allergy (J. Lecomte). The metabolism of magnesium (M. J. Dallemagne) and that of strontium and radiostrontium (J. Goffart) follow, and the second volume ends with a chapter by J. Lecomte on the toxicity of alkaline earth metals.

This outline of the contents of the two volumes gives some indication of the scope of the work. Prof. Z.-M. Bacq has done his work of planning and co-ordination admirably and is to be congratulated on having persuaded so many distinguished Belgian workers to join him in this enterprise. All the chapters are of high quality and present in a clear manner a wealth of information on a field of wide interest. There are extensive lists of references at the ends of the chapters which add greatly to the usefulness of the book. Moreover, each of the two volumes is self-contained, with its own author and subject index. The drawings are excellent and the volumes beautifully produced.

The coverage is so wide that workers in a great number of disciplines will find these two volumes very useful indeed. However, in order to enjoy them to the full, the reader should have a competent knowledge of French, all chapters being in that language. Moreover, if he wishes to have the two volumes on his own shelves, he needs a respectable bank balance, the price of the two volumes being £30 5s. 8d.

ELEANOR ZAIMIS

RESEARCH IN PHOTOGRAPHY

Mitteilungen aus den Forschungslaboratorien der Agfa-Gevaert AG, Leverkusen-München
Band IV. Pp. viii+474. (Berlin, Heidelberg and New York: Springer-Verlag, 1964.) D.M. 96.

VOLUME 4 of *Mitteilungen aus den Forschungslaboratorien der Agfa-Gevaert AG*, like its predecessors, comprises a selection of papers originating from the Agfa Laboratories in Leverkusen and Munich. It represents a cross-section of the work in recent years of the Agfa research workers in the field of photographic and related science and technology.

A total of 35 individual papers, 13 of which have previously been published in other journals, cover the following ground: thermo-dynamic studies of the basic photographic process and a review of the present theories of spectral sensitization; investigations of the growth and crystal habit of silver halide microcrystals and of the composition and stability of the latent image. Other papers give predominantly theoretical treatment of the mechanism of various reactions which are relevant to the photographic process and of development. Another section deals with the properties of the processed photographic image and includes papers on the sensitometry as well as on statistical investigations of tolerances of reversal colour films. This part also includes no less than six papers in a field of growing importance which describe investigations into the performance characteristics of photographic layers in terms of the modulation transfer theory.

Papers in the field of organic chemistry range widely: the reaction of coupling compounds with *p*-phenylene-diamines, resulting in the formation of colourless products and of dyes; optical sensitizing dyes; new developer substances; reactive dyes for gelatine and analytical chemistry. Two further contributions are concerned with the preparation and properties of magnetic tape. Finally, there are contributions in the camera and equipment field; on the spectral sensitivity distribution of photo-electronic receivers and on the efficiency of illumination systems. The standard of the experimental work and of its presentation is high throughout. Among the many experimental techniques used, electron-microscopic photography deserves special acknowledgment.

The volume has been edited by E. Klein and R. Matejec. Prof. Klein, who is the research director of the Agfa part of Agfa-Gevaert, is co-author of several of the papers. Other contributors include such well-known names as R. Matejec, E. Moisar, J. Eggers, W. Behrendt, G. Langner and W. Püschel.

This volume is dedicated to F. Gajewski, who initiated Agfa research in the photographic field in the 1930's. It is in this context that one may understand the reasons for publishing volumes of this kind which cover such a wide range of subject-matter; that is, to demonstrate within and outside the company the value of research work which does not always become apparent in the company's products. By the nature of their work, most scientists in the field would be interested only in some section or sections of this volume, and the majority would be equally well served if the individual papers could appear in the appropriate journals, as many of them have done already.

K. O. GANGUIN

A HUMANISTIC TECHNOLOGY*

By VICE-ADMIRAL H. G. RICKOVER, C.B.E.†
U.S. Navy

CHANGE is now part of life in all industrially advanced countries—continuous, rapid, all-pervading change. The ultimate cause of this unsettling situation is the explosion of science: factual knowledge doubles every decade or so. Its direct cause is the technological revolution: new knowledge is put to practical use about as rapidly as knowledge itself expands.

The impact of technology on individuals and on society at large is profoundly affected by the attitude of the public and of its leaders toward technology; that is, by prevailing concepts of what technology is and what purpose it should serve.

When technology is believed to be a force with a momentum of its own that puts it beyond human direction or restraint, it may become a Frankenstein destroying its creator. But when it is viewed humanistically, in other words, as a means to human ends, it can be made to produce maximum benefit and do minimum harm to human beings, and to the values that make for civilized living. It may even enable man to become more truly human than it has ever been possible for him to be. Of technology it can be truly said that it is not "either good or bad, but thinking makes it so".

I propose to show there is a tendency in contemporary thinking to regard technology as an irresistible force rather than a tool. The tendency is more pronounced in some countries than in others but is observable wherever there is rapid technological progress. Since it encourages the use of technology in ways that on balance are harmful, this point of view should be replaced by a humanistic attitude—an attitude which looks on technology as an instrument created for no other purpose than to serve man.

There is no need to belabour the point that technology, properly used, can be of great benefit. But there is need to bring out the potential harm which technology, improperly used, may cause. My concern is with attitudes, for I believe it is attitudes that determine what we do with technology.

The part played in the formation of popular attitudes by all media of communication—books, newspapers, journals, radio, television—is too obvious to need comment. Apart from formal education, which for most people ends at the threshold of maturity, these media bear the respon-

sibility of supplying the factual information men must have if they are to arrive at rational judgments on issues that interest them as individuals, or concern them as citizens of a democratically organized society. Many of these issues contain technological elements. In presenting them to the public, it is important to assign these technological elements their appropriate place. Therefore, those involved with communications (using the term in its broadest connotation) must themselves have a clear conception of the nature of technology and of its proper role.

Technology has been defined as "covering the field of how things are commonly done or made", and, somewhat more broadly, as "what things are done or made". It is a modern term, but we are in the habit of using it retroactively. We apply it to the techniques of a pre-industrial metal worker no less than to those of a modern metallurgist. Yet modern technology differs significantly from that of the past in being largely based on science, that is, founded on accurate knowledge of the workings of Nature. Earlier techniques, arts, skills were almost entirely empirical. Because of his knowledge of Nature, man, through technology, is now able to alter his material environment, the material conditions of life. If these changes are to be beneficial, not harmful, technology must be managed as a humanistic enterprise.

By boring into the secrets of Nature, scientists discover keys that can be used to unlock powerful forces. Technology is concerned with putting these forces to practical use. The apparatus set up for this purpose is huge and complex, difficult for laymen to understand. Yet the basic nature and purpose of technology are not beyond the comprehension of ordinary citizens.

Technology is tools, techniques, procedures, things; the artefacts fashioned by modern industrial man to increase his powers of mind and body. Marvellous they are, but let us not be overawed by these artefacts. Certainly they themselves do not dictate how we should use them, nor, by their mere existence, do they authorize actions that were not anteriorly lawful. We alone bear responsibility for our technology. In this, as in all our actions, we are bound by the principles governing human behaviour in our society. Ethics, I need scarcely say, are not only personal but also social.

This surely must be obvious to any reasonable man. Yet it cannot be over-emphasized, for a considerable body of opinion propagates what comes close to being the opposite view. The notion is widespread that, having wrought vast changes in the material conditions of life, technology perforce renders obsolete traditional concepts of ethics and morals, as well as accustomed ways of arranging political and social relationships. Earnest debates are at present taking place as to whether it is possible to act morally in the new technological society, and proposals have been made—quite seriously—that science must now replace traditional ethics. We have here a confusion of means with ends that should be cleared up.

The laws disclosed by science must of course be heeded by those who wish to exploit scientific discoveries; in his technological activities man is bound by the laws of science. But it does not follow that he is bound by the laws of science in his purely human relations as well. "Science", wrote Vannevar Bush, "has come a long way, in delineating the probable nature of the universe that surrounds us, of the physical world in which we live, of our own structure, our physical and chemical nature.

* Substance of a Granada Lecture of the British Association for the Advancement of Science, delivered in Guildhall, London, on October 27. This Lecture does not necessarily reflect the view of the U.S. Secretary of the Navy or the Department of the Navy.

† Vice-Admiral Hyman G. Rickover is head of the Division of Nuclear Propulsion in the U.S. Navy Bureau of Ships and director of the Division of Naval Reactors, U.S. Atomic Energy Commission.

During the Second World War he was head of the Electrical Section of the Navy's Bureau of Ships, and at its conclusion was assigned to the Atomic Submarine Project. He took the lead in the design, development and construction of nuclear propulsion systems for submarines and other naval ships, the first of which, the submarine *Nautilus*, was launched in 1954. To-day the U.S. Navy has three nuclear-powered surface vessels, including the giant aircraft carrier *Enterprise*, and a large number of nuclear-powered hunter killer and *Polaris* submarines. Although well past retiring age, Admiral Rickover has been retained in service and remains personally responsible for the whole of this nuclear propulsion programme. He has also been charged with the responsibility of developing large-scale atomic power plants to generate electricity.

In addition to a direct concern with every detail of these nuclear-power programmes, Admiral Rickover has given much time and thought to problems of American education, which he has compared with school systems in other countries, including Great Britain, in three books and in several reports to the House of Representatives Appropriations Committee.

Among the many honours and awards which have come to Admiral Rickover are the very rare Congressional Gold Medal, which he received in recognition of his work in the nuclear-power programme field, and the Enrico Fermi Award, where his name joins a distinguished list including John von Neumann, Ernest Lawrence, Glenn Seaborg, and J. R. Oppenheimer. Among many honorary degrees which he has received is a D.Sc. of the University of Birmingham; he was made an honorary C.B.E. in 1948.

It even enters into the mechanism by which the brain itself operates. *Then it comes to the question of consciousness and free will—and there it stops.* No longer can science prove, or even bear evidence. Those who base their personal philosophies or their religion on science are left, beyond that point, without support”.

Through technology man has been relieved of much brutal, exhausting, physical labour as well as boring routine work; he has been provided with numerous mechanical slaves who do certain kinds of work faster, cheaper and more efficiently than people. Why should the ease and affluence made possible by technology affect precepts that have guided Western man for centuries? This may brand me as old-fashioned, but I have not yet found occasion to discard a single principle that was accepted in the America of my youth. Why should anyone feel in need of a new ethical code because he is healthier or has more possessions or more leisure? Does it make sense to abandon rules one has lived by because one has acquired better tools for doing one's work?

Tools are for utilizing the external resources at our disposal; principles are for marshalling our inner, our human resources. With tools we alter our physical environment; principles serve to order our personal life and our relations with others. The two have nothing to do with each other.

It disturbs me to be told that technology ‘demands’ an action the speaker favours, that ‘you cannot stop progress’. It troubles me that we are so easily pressured by purveyors of technology into permitting so-called ‘progress’ to alter our lives, without attempting to control it—as if technology were an irrepressible force of Nature to which we must meekly submit. If we reflected, we might discover that not everything hailed as progress contributes to happiness; that the new is not always better nor the old always outdated.

Perhaps we are receptive to these arguments because we tend to confuse technology with science. Not only in popular thinking but even among the well-informed the two are not always clearly distinguished. In consequence, characteristics pertaining to science are attributed to technology. The etymology of the word may contribute to this confusion. Its suffix lends to technology a false aura—as if it signified a body of accumulated, systematized knowledge, when in fact the term refers to the apparatus through which knowledge is put to practical use. The difference is important.

Science has to do with discovering the facts and relationships of observable phenomena in Nature, and with establishing theories which serve to organize masses of verified data concerning these facts and relationships. Because of the care scientists take to verify the facts supporting their theories, and their readiness to alter theories when new facts prove an established theory to be imperfect, science has great authority. What the scientific community accepts as proved is not questioned by the public. No one disputes that the Earth attracts the Moon, or that atomic fission produces energy.

But technology cannot claim the authority of science. It is properly a subject of debate, not alone by experts but by the public as well. It has proved anything but infallibly beneficial. Much harm has been done to man and Nature because technologies have been used with no thought for the possible consequences of their interaction with Nature. A certain ruthlessness has been encouraged by the mistaken belief that to disregard human considerations is as necessary in technology as it is in science. The analogy is false.

The methods of science require rigorous exclusion of the human factor. They were developed to serve the needs of scientists, whose sole interest is to comprehend the universe; to know the truth; to know it accurately and with certainty. The searcher for truth cannot pay attention to his own or other people's likes and dislikes, or to popular ideas of the fitness of things. This is why

science is the antithesis of ‘humanism’, despite the fact that historically modern science developed out of and parallel to the humanism of the Renaissance.

What scientists discover may shock or anger people—as did Darwin's theory of evolution. But even an unpleasant truth is worth having; besides, one can choose not to believe it. It is otherwise with technology. Science, being pure thought, harms no one; therefore it need not be humanistic. But technology is action, and often potentially dangerous. Unless it is made to adapt itself to human interests, needs, values, and principles, more harm than good will be done. Never before, in all his long life on Earth, has man possessed such enormous power to injure his human fellows and his society as has been put into his hands by modern technology.

This is why it is important to maintain a humanistic attitude toward technology; to recognize clearly that, since it is a product of human effort, technology can have no legitimate purpose but to serve man—man in general, not merely some men; future generations, not merely those who at present wish to gain advantage for themselves; man in the totality of his humanity, encompassing all his manifold interests and needs, not merely some one particular concern of his. Humanistically viewed, technology is not an end in itself but a means to an end, the end being determined by man himself in accordance with the laws prevailing in his society.

A word may be in order concerning the disparate meaning of the word ‘law’, depending on whether it is used in the ordinary sense—which is also the original sense of the word—or by scientists. Law, as commonly understood, refers to those rules of human conduct prescribed and enforced by society. The scientists have appropriated the term. They use it to describe regularities exhibited by physical phenomena—the rules by which the cosmos governs itself. In the transition, the word has taken on a new meaning.

Law that governs human society is not the result of scientific method but of wisdom and experience, of consensus as to what is just and fair. In autocracies, law is what the ruler wishes it to be and what he is able to enforce by naked power. The purpose of human law is to resolve conflicts by the application of definitive rules. These rules are always debatable and can be changed when there is public demand for a change or when the rule-maker desires them to be changed.

From the layman's point of view, what the scientist calls law is fact, rather than law—immutable fact. Or, if you prefer, it is law operating in a sphere where man exercises no influence. He cannot alter the laws of the cosmos; he can only discover them. It would be pointless for him to debate these laws; he must accept them. A law of science expresses mechanical regularity where no choice of action, no free will, comes into play; it deals with constancy of behaviour in Nature; it has relevance for man only because it makes the universe more comprehensible to him and, by disclosing how Nature works, allows him to utilize the forces of Nature for his own purposes.

When we make use of these forces, we must of course heed the laws of science which describe their behaviour; they are laws we cannot bend to our will. But we must likewise heed the man-made laws of our society, for technology is action which affects fellow human beings. Technology straddles, as it were, the law of the cosmos and the law of man; it is subject to both. Much confusion in popular thinking arises from this fact. The two laws are confounded. Or, to put it differently, they are thought to be part of a single system of law so that one or the other must perforce take precedence.

Ever since science discovered that the Earth is not the centre of the cosmos, as had been maintained by the highest human authorities, we have been learning painfully that the laws of science cannot be overturned by human fiat. To-day, acceptance of duly authenticated

scientific theories or laws is common practice in enlightened countries. Occasionally, an attempt is made to muzzle scientists whose findings contravene accepted dogma—as when the U.S.S.R. forced geneticists to conform to the party line, or when some backward community in the West forbids the teaching of evolution because this conflicts with the community's religious dogma. But these are rare cases, and no reasonable person condones them.

It has taken a long time to attain this rational attitude toward science, and we are conscious of the consequences of intolerance in the past. Perhaps this is why we have been excessively tolerant toward those who claim the right to use technology as they see fit, and who are wont to treat every attempt by society to regulate such use in the public interest as if it were a modern repetition of the persecution of Galileo.

Assuredly, we have the right to use the instrumentality of law and of government to protect ourselves against technological injury. Yet this simple truth is obscured by the effective way in which opponents of protective measures play on the layman's respect for science—in a conscious or unconscious attempt to brainwash the public so it will accept their argument without debate. When attacking legislation that would restrain the user of technology, it is common practice to argue as if at issue were acceptance of a law of science. Yet what is being discussed is not science but the advisability or legality of the technological exploitation of science. The public would not be deceived by such arguments if it clearly understood the fundamental difference between science, which is pure knowledge, and technology, which is action based on knowledge.

To guard against being misled, one should cultivate an attitude of scepticism whenever the word science is used. Is it science that is being discussed or is it technology? If technology, the question at once arises whether the proposed action is legally permissible and socially desirable. These are matters which lie outside science. Just as the law of the cosmos cannot be overturned by human fiat, so is human law supreme within its own proper sphere of operation. Technology must therefore conform to that most basic of all legal maxims, the 'mutuality of liberty'; the principle that one man's liberty of action ends where it would injure another. Without this maxim, freedom would be a barren privilege.

Humanistically viewed, technology can have no legitimacy unless it inflicts no harm. Granted this premise, the prerequisite for users of technology is—or ought to be—that they comprehend and respect the laws of science applicable to their particular technology; that they exercise a prudent man's care in assessing the probable consequences of this technology; and, should it be potentially harmful, that they abstain from using the technology until they have found ways to render it harmless.

Whether or not a particular technology has harmful potentialities ought not to be decided unilaterally by those who wish to use it. Destructive technologies are often highly profitable for those promoting them. They have a vested interest in the technology; it may give them money, reputation, power. They are an interested party to the conflict between private and public interest which every potentially harmful technology poses. Moreover, they are nearly always practical men more knowledgeable about efficiency in using a technology than about the legal and scientific implications of such use.

A broader range of intellectual power should be brought to bear on the whole question of technological exploitation of scientific knowledge. Purely practical considerations should be supplemented with scholarly knowledge of long-range consequences; private interest in efficiency with public interest in safety. The automatic discipline of a free market—where it still exists—does not include side-effects and long-range consequences; it merely reflects consumer preference for a product that appears useful and is reasonably priced. The consumer is too ill-informed about safety to make his opinion felt.

I think one can fairly say that the practical approach to a new scientific discovery and its utilization through technology is usually short-range and private, concerned only with ways to put the discovery to use in the most economical and efficient manner, little thought being given to its ultimate consequences. The scholarly approach—if I may use this term—is long-range and public; it looks to the effects which a new technology may have on people in general, on the nation, on the world; on present and future generations. Of course there are men who combine the two approaches and you find them among people whose primary interest is practical, no less than among those whose primary interest is scholarly. Both approaches are necessary to illuminate the problem and help solve it. To exclude the one or the other prevents finding the way to a humanistic technology.

I can best illustrate what I want to bring out by a simple example. Commercial deep-sea fishing can be done so efficiently with modern techniques that a few enterprises could rapidly sweep the oceans free of commercial fish: and this is what the fishermen of all nationalities wish to do. As practical men they are interested only in using technology to increase their catch, preserve it and get it to market as speedily as possible. In pursuing this short-range private objective, they have been quite ingenious. Figuratively speaking, the world's marine scholars have stood by wringing their hands at the fishermen's 'practical' folly. To the scholars it has been incomprehensible that rational human beings should fail to see that in the end more can be taken from the sea if fishing conforms to sensible conservation measures which permit the species to reproduce itself.

We witness at the moment the end of one of the saddest stories of misuse of technology by greedy fishing interests. Unless "the myopic stupidity of commerce"—as the *New Scientist* calls it—is curbed by really effective international action, the great whales—the blue, the finback, the sperm—will soon disappear forever, victims of man's 'practical' folly.

These and other whales once populated the high seas in immense numbers. For hundreds of years whaling remained a reasonably fair contest between man and the intelligent, swift-moving mammals he hunted. Modern technology has turned it into brutal genocide. The culprits are the whaling fleets of Norway, Japan and the U.S.S.R., last remnants of what once was a large company of whaling fleets from many nations. One by one they ruined themselves by destroying the marine resources on which their livelihood depended. Yet nothing has been learned from the lessons of the past.

The International Whaling Commission, in 1964, advised that, unless the catch were drastically reduced for a number of years, the whales would not reproduce themselves in sufficient numbers to support continued commercial fishing. The whalers rejected the warning (the Japanese called it "over-emphasized biology") and agreed among themselves to catch twice the limit proposed by the Commission, only to find the stocks already so depleted that they could not even meet their own 'limit'. Blindly pursuing what they doubtless consider an eminently practical objective, maximum profit to-day, they are wiping out the very resources that could insure them a profit to-morrow.

Practical considerations apart, is anyone—are fifteen fishing fleets, 250 ships in all—justified in using technology to exterminate a species which has existed on this Earth for millions of years—the largest animal the world has ever seen? Do we know that our descendants will not at some future time have need of these mammals? R. A. Piddington, in his book *The Limits of Mankind*, remarks that nobody knows what the biological consequences of the extermination of such whales are likely to be. "But if nearly a million of these huge animals, with their enormous appetites, can be removed in a single generation from the balance of marine life without causing violent repercussions,

all our previous experience of this subject has given us the wrong answers.' He notes that the sperm whale is the only creature eating "that nightmarish monster the giant squid", and suggests that one consequence of exterminating this huge whale may be a tremendous increase in the population of giant squid and their penetration close to our shores—not a pleasant prospect.

Technological damage to deep-sea fisheries happens to be an international problem, therefore particularly difficult to solve. But quite as disastrous in its ultimate consequences is the discharge of poisonous waste products by industrial plants using rivers and lakes as their private sewers. Valuable national fisheries have been ruined, not to speak of harm done to those who may eat fish poisoned by the waste products of new technologies. Detergents pose a similar problem. They are cheaper to manufacture than soap, hence more profitable to the producer, and they are preferred by consumers for their superior cleansing capacity. But, discharged into waterways, their organically undissolvable chemicals have proved particularly intractable pollutants.

Irretrievable damage has been done by those who use technology without giving thought to its effect on our environment. Waste products, carelessly emitted, create a massive problem of soil, water and air pollution: we may be damaging the atmosphere permanently by changing its chemical composition. Wholesale slaughter of wild animals upsets the ecology with consequences we cannot even fathom as yet. In some places the contours of the land are being changed by strip mining which gouges out chunks of earth and rock with their top soil and vegetation, leaving behind a desolate lunar landscape.

In so far as damage is still remediable—and much of it can never be undone—it must be remedied by public action, at taxpayers' expense. The total cost to the public of private carelessness and wilfulness in the use of technology will be enormous.

Experience shows that, by itself, the legal maxim of 'the mutuality of liberty' will not prevent premature commitment to technologies that may later prove harmful. The maxim must be implemented by preventive public action—action of the kind that has long been operative in the field of public health. There is need for laws requiring that before a particular technology may be used, reliable tests must have been made to prove it will be useful and safe. A few such laws are already on the statute books; more are needed. But we rarely get positive action until a human tragedy dramatizes the need for protection. So was it once, too, with preventive public health measures.

It will be remembered that they received their major impetus from the great cholera invasions of the past century. These were themselves a result of new technologies in transportation which enormously speeded the movement of persons and goods. The time-interval for travel from the areas of endemic cholera in the Far East to Europe and America was reduced below the incubation period of the disease. Without strong measures, the West could not protect itself against disease carriers coming from the East. These measures were bitterly fought because they impeded the movements of people and merchandise. It took repeated major epidemics to compel action.

In the United States there are preventive laws protecting the public against dangerous drugs. The first law, bitterly fought by the pharmaceutical interests, did not pass until a major tragedy had occurred—the death of a considerable number of patients who had taken a drug which was effective in the treatment of their particular disease, but had unforeseen side-effects proving fatal to some. After much procrastination, a second, more stringent law was passed, but not until the uproar over the thalidomide babies caused the legislators to respond with alacrity.

Though a technology may clearly harm paramount human values, restraining laws will not be forthcoming unless public demand is sufficiently vocal and persistent to wear down the opposition of those with a vested interest in the harmful technology. Opposition tactics follow a pattern that is monotonously repeated whenever the attempt is made to regulate a technology in the public interest. It is well to familiarize oneself with the pattern.

I have mentioned efforts to confuse the issue by arguing as if a law of science were at issue when in fact the proposed legislation deals with technology, not science. If this argument fails, the need for the proposed law is then categorically denied. Warnings of scientists are rejected as 'unproved' and 'exaggerated'. Later, when these prove to have been entirely correct, the argument shifts from the substantive question of whether a technology is harmful to an attack on the legitimacy of any kind of protective legislation. Such legislation would violate basic liberties, it is claimed; it would establish government tyranny and subvert free democratic institutions. If all this proves futile and legislation is imminent, there will be urgent demands that it be postponed until 'more research' can be undertaken to establish the appositeness of the proposed law.

These delaying tactics are highly effective. It takes firm commitment to a humanistic technology to push through needed legislation as well as thorough understanding of the filibustering tactics of opponents, and great skill in combating these tactics. No wonder public opinion and the law have nowhere fully caught up with those who misuse technology. Often as not they escape with impunity, no matter how gravely they injure man or society.

I suggest that, as a special public service, those trained in the law take on the task of working for better protection against technological injury. This is a new and fruitful area in which lawyers could make important contributions to human welfare—an area which requires no revolutionary change in the political or economic structure of society, merely greater precision and fuller implementation of the traditional principle that injuring the health or causing the death of human beings is unlawful. The term health should not be limited to physical health but should include psychic health and protection of the human personality as well. New technologies based on the uncertain 'science' of the social sciences involve snooping into the inner recesses of the human mind, personality testing and pseudo-scientific manipulation of human beings. When they are imposed as conditions of employment or otherwise partake of an element of compulsion, these technologies should be regulated or outlawed entirely.

Much more thought should be given to technological interference with the balance of Nature and its consequences for man, present and future. Let me give one more example of the harm such interference may cause.

To-day we have new technologies for the destruction of insect pests and weeds. Their use is profitable for the manufacturers of pesticides and weed killers; it is helpful to farmers who are able to get better crops, reduce human labour, and produce at greater profit; it benefits consumers who are offered a wider variety of food at less cost. Here is a classic case of what technology can do for us. Unfortunately, we have left out of consideration the balance of Nature. If used improperly, these pesticides and weed killers will poison soil, crops, birds, animals, fish and eventually man. In her book *Silent Spring*, Rachel Carson spoke out eloquently against committing this ecological sin.

Ecologists constantly warn us that when the balance of Nature is upset, everything in Nature is threatened, including man himself. It seems certain that unless he sets limits to his destructive instinct, man will ultimately exterminate all wild life. He will then be left alone on Earth with his domesticated animals and with swarms of insects and germs; alone in a world he has fashioned in the image of his technology.

Insects have flourished on this Earth for 350 million years or more and outnumber man by a factor of hundreds of thousands. They are better adapted to survive new technologies than larger animals. A few specimens always survive whatever poison may be administered to them. Multiplying with fantastic rapidity, they then present man with a harder strain which he must attack with still more poisonous pesticides. The true victims of this endless battle are not the insects but other living creatures, our natural allies in the war against insects. Piddlington closes his chapter on the balance of Nature with a synthetic proverb which doubtless makes no sense to practical men but will be readily understood by those who comprehend the ABCs of ecology: "Whoever destroys an elephant creates a thousand rats, or a million flies".

The examples I have given show that to make technology safe, we must have protective laws; that enactment of such laws depends on a humanistic attitude toward technology on the part of significant segments of the public and its leaders. But more is needed. Law and public opinion nearly always lag behind the swift development of new technologies. Therefore, what is additionally needed is more informed and responsible thinking among those who manage technologies. This can best be brought about by 'professionalizing' the decision-making process in technology. Experience has shown that in the hands of professional persons technology is managed with greater concern for human welfare than when it is controlled, as at present, by non-professionals. The classic example is medicine.

Of all technologies, that of the physician has benefited man most and harmed him least. The stringent standards set by the profession and by society for the education and professional conduct of physicians accounts for this happy circumstance. Not only is no one permitted to practise who has not given proof of his competence, but physicians must also be broadly, liberally, humanistically educated men and women. This gives them perspective in evaluating their professional actions, an ability to see these actions against a humanistic background. Moreover, they operate under a code of ethics which requires them to place the needs of patients above all other considerations.

We owe to Greece the noble idea that special knowledge and skill ought to be used humanistically, instead of merely for personal aggrandizement or power, or as a means of extracting maximum gain from those in need of the services of men possessing special expertise. It was a novel idea at the time, and remains unknown to this day in many regions of the world. Even among the people of Western civilization the precept is rarely followed outside medicine and a few other 'learned' or liberal professions. Most human affairs are conducted on the old Roman maxim of *caveat emptor*.

I have long believed that we should come appreciably closer to a humanistic technology if engineering were practised as a humanistic profession, and if, in consequence, engineers were accorded the professional independence granted members of liberal professions. I feel certain engineers would then find it possible to act with the same sense of professional responsibility and service to humanity which is characteristic of good physicians. It may be that in some countries engineering has already attained the status of a truly liberal or humanistic profession. But I doubt if this is the case in Great Britain or the United States.

Engineering now stands at the threshold; there is no reason why it should not enter the liberal professions. It has as its theoretical foundation a body of systematic knowledge, an academic discipline as rigorous and extensive as that of other learned professions. It has a highly developed technique for applying this specialized knowledge to practical problems. But to-day there is no absolute requirement that an engineer must be a liberally educated man, nor has engineering adopted the kind of ethical code that governs the older professions of medicine and law.

It is because of the 'professional' characteristics I have here stated that members of the 'learned' professions demand and are accorded professional independence. "The essence of professions," wrote Abraham Flexner, an expert in this field, "resides in the application of free, resourceful, unhindered intelligence to the comprehension of problems." Service ceases to be professional if it has in any way been dictated by the client or employer.

The role of the professional man is to lend his special knowledge, his well-trained intellect, his dispassionate habit of visualizing problems in terms of fundamental principles to whatever specific task is entrusted to him. Professional independence is not a special privilege but rather an inner necessity for the true professional man; it is a safeguard for his employer and for the public as well. It is what chiefly sets him apart from the skilled technician.

This independence of professional judgment has not yet been accorded the engineer. He still has to win it for himself. Engineers are nearly always salaried employees rather than self-employed, which makes it all the more essential that they gain professional status. Where engineers and physicians work in the same organization, it happens not infrequently that the most experienced engineer's professional judgment will be overruled by a lay superior, while no one would think of dictating to a physician, no matter how young and inexperienced he might be. Yet the university-trained engineer is as competent a professional in his field as is the physician. The difference lies in the determination of the medical profession to resist lay interference and its success in winning this point, while the engineering profession has shown little determination, and therefore has had little success.

I speak of this with feeling. As is known, my work is in one of the new technologies: one that is dangerous unless properly handled. I am frequently faced with the difficulty of convincing administrative superiors that it is not safe for them to overrule their technical experts. Here is a case in point.

A superior once asked me to reduce radiation shielding in our nuclear submarines. He said the advantage of getting a lighter-weight reactor plant was worth risking the health of personnel. It was not possible to make him see that such a concept could not be accepted; that, moreover, where radiation is involved, we are dealing not just with the lives of present-day individuals but with the genetic future of all mankind. His attitude was that we did not know much about evolution and if we raised radiation exposures we might find the resulting mutations to be beneficial—that mankind might 'learn to live with radiation'. As one may surmise, I did not reduce the thickness of the shielding.

The British and the Americans are fortunate to live in countries so organized politically that individuals enjoy the greatest possible freedom consistent with their obligations as members of a civilized society. But freedom always comes at a cost. As citizens of a free, self-governing society, we are individually and severally responsible for the quality of our society. The values making for civilized life are neither created nor preserved without continuous effort. In a democracy it is the people themselves who must make this effort.

A final word needs to be said concerning the impact of technology on the political institutions of a free society.

By making it possible for affluence and leisure to be spread over large segments of the population—theoretically over all the people—technology gives support to democratic institutions. We are approaching a situation comparable to that of Athens 2,500 years ago, where every citizen was an active participant in the governance of his city State. He would not have had the leisure to do this had there not been slavery. To-day, each of us has many more mechanical slaves than the Athenian had live

ones. We have at least as much leisure as he had to devote to public affairs.

The Athenian, however, dealt with public issues which were not beyond the comprehension of ordinary citizens. Modern democratic citizens, on the other hand, are faced with issues which are extremely difficult for laymen to understand. They must depend, to an extraordinary degree, on the advice of experts. Whether such advice is competent as well as impartial is often hard to judge. Much of the difficulty arises from the complexities technology introduces into modern life. To the extent that it renders public issues incomprehensible to ordinary citizens, technology undermines democratic institutions.

Technologically created affluence and leisure make it possible for Great Britain and the United States—in fact all advanced industrial countries—to socialize the cost of education, thus giving every citizen a chance to become as educated as his God-given talents and his determination allow him to be. The opportunity is there, but will it be seized?

We do not yet know whether people may not prefer to live the life of the idle rich—as they imagine it to have been—pursuing fun and games, not bothering about becoming educated or meeting their public responsibility, or whether they will decide to emulate those—and there were many in all ages—who considered material comfort and leisure a trust, to be used for improvement of self and society. We have a choice, but unless democratic electorates raise their competencies to a higher plateau, they will discover that they cannot effectively control either their government or their technology.

It is obvious that a society's technological level determines the range of occupational skills for which there is effective demand. The higher the level, the smaller the demand for unskilled labourers, the greater that for intelligent, well-educated professional persons, semi-professionals, skilled technicians. Less obvious is the fact that technology also sets a lower limit to the educated intelligence citizens must have if they are to meet their public responsibilities—a sort of Plimsoll mark. Those who fall below this mark are precluded from participating in the public dialogue through which consensus is formed in free societies; they are precluded simply because they do not understand public issues involving technology. Democracy is not viable if too many fall below this mark.

In an oversimplified way, one might say that in a free society citizens have private liberties and public responsibilities; they safeguard their private liberties by faithfully discharging their public duties. Any diminution,

whatever its cause, of the individual citizen's ability to think independently about matters that determine the shape of his society, any lessening of his participation in its governance, makes society less free, democracy less viable.

How we use technology affects profoundly the shape of our society. In the brief span of time—a century or so—that we have had a science-based technology, what use have we made of it? We have multiplied inordinately, wasted irreplaceable fuels and minerals and perpetrated incalculable and irreversible ecological harm. I have thought much about this, and I can find no evidence that man contributes anything to the balance of Nature—anything at all. On the strength of his knowledge of Nature, he sets himself above Nature; he presumes to change the natural environment for all the living creatures on this Earth. Do we, who are transients and not overly wise, really believe we have the right to upset the order of Nature, an order established by a power higher than man?

These are complicated matters for ordinary citizens to evaluate and decide. How in future to make wiser use of technology is perhaps the paramount public issue facing electorates in all industrial democracies; a problem difficult enough in itself but rendered still more so by the strategies of those who wish to continue using harmful technologies.

As I said at the beginning, the communications media could render great service by providing the public with a balanced view of the issue. Reportage which consistently takes a humanistic attitude toward technology would be of immense help. So would consistent stress on the propriety of laws to prevent technological damage. It cannot be said too often that Government has as much a duty to protect the land, the air, the water, the natural environment of man against such damage, as it has to protect the country against foreign enemies and the individual against criminals; conversely, that every citizen is duty-bound to make an effort to understand how technology operates and what are its possibilities and limitations. All this is necessary if technology is to be assigned its proper place in human affairs, if it is to be made humanistic.

A free society centres on men. It gives paramount consideration to human rights, interests and needs. But, once ordinary citizens come to feel that public issues are beyond their comprehension, a pattern of life may develop where technology, not man, would become central to the purpose of society. If we permit this to happen, the human liberties for which mankind has fought, at so great a cost of effort and sacrifice, will be extinguished.

MATERIALS SCIENCE AND ENGINEERING AT THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY

WITH the official opening and dedication of the new interdisciplinary laboratory of the Center for Materials Science and Engineering (Fig. 1) on October 1, 1965, a new phase in the long-standing development of research and teaching in this field was inaugurated at the Massachusetts Institute of Technology. The principal speaker at the dedication of the new building was Dr. William O. Baker, vice-president of research, Bell Telephone Laboratories. The building was named the Vannevar Bush Building in recognition of the outstanding contributions to science and engineering and to their utilization to meet urgent national needs of Dr. Vannevar Bush, honorary chairman of the Corporation of the Massachusetts Institute of Technology.

Other speakers at the dedication included President Julius A. Stratton, Dean Jerome B. Wiesner of the School of Science, Dean Gordon S. Brown of the School of Engineering and Dr. James R. Killian, jun., chairman

of the Corporation, who presided. Representing the Advanced Research Projects Agency of the Department of Defense was its director, Dr. Charles M. Herzfeld. It was a happy combination of support from the Advanced Research Projects Agency and the Massachusetts Institute of Technology Second Century Fund with special assistance in financing from the Alfred P. Sloan Foundation of New York which made the building possible.

Materials science and engineering, both in their fundamental and practical aspects, have been studied for many years at the Institute. The Departments of Mechanical, Electrical and Chemical Engineering and the Department of Metallurgy have for many years been investigating the properties of traditional metals, ceramics, glasses and other materials used in the course of their professional activities, and more recently new materials such as semiconductors and polymers have been added to the list. The basic science departments, especially physics and chemistry,

have long had as part of their programme fundamental investigations of the cohesive properties of solids and of the phenomena of electrical and heat conduction in various materials as well as of their magnetic and optical properties. There is now scarcely a department within the Schools of Science, Engineering and Architecture which is not involved in materials research and teaching in a major way.

To give a focus for all this activity the Center for Materials Science and Engineering has been established, and also to take advantage of the interdisciplinary character of much materials research. This arose from a strong desire to strengthen the programme of materials research to meet the urgent demands of modern technology both through research achievement and through the production of well-trained engineers and scientists in this field. The benefit obtained by contact of research workers from different disciplines is well recognized in a number of great industrial and Government laboratories; the Interdisciplinary Laboratory for Materials Science and Engineering has been built to encourage such interaction in a university environment.

The new laboratory building provides a number of central facilities which have always been envisaged as the cement which would bind the Center together. Modern equipment for materials research is expensive, and centralization is the only way to provide some of this equipment. The facilities include equipment for preparation, purification and evaluation of various groups of materials. This equipment is usually in charge of a professor, and four main groups of materials are provided for at the moment: metals, insulators, semiconductors and composite materials such as ceramics. A central analytical laboratory provides up-to-date chemical methods of evaluation, while physical methods include X-ray analysis, optical and electron microscopy, and electron micro-probe analysis. Some expensive pieces of

equipment used primarily by individual professors for their own research are also available some of the time for use by others. These facilities are also backed by the close association of the laboratory with other laboratories of the Institute, such as the Laboratory for Nuclear Science, which provides facilities for the use of neutron scattering, the National Magnet Laboratory, which provides very high magnetic fields, and the Spectroscopy Laboratory with its excellent instruments and wide variety of optical techniques.

The research programme in the new laboratory is supported by a number of Government agencies and industrial organizations through individual contracts and grants to professors, but a substantial part is supported by the Advanced Research Projects Agency (ARPA). This research covers a wide variety of topics, too numerous to be detailed here, but falling generally into the following categories: basic physics and chemistry of solids, study of materials of interest in electronics and optics, research into the factors that determine the ultimate strength and mechanical properties of materials under a wide variety of conditions. Of particular interest are materials for use at high temperatures and pressures. Special materials such as high-field superconductors, and laser materials, are also included.

Although the research programme to be carried out in the new building represents a substantial fraction of the total materials research effort at the Institute, it is only part of a considerably larger activity in various departments and in other laboratories. It is planned to concentrate a good deal of the more fundamental research on materials science and engineering in the new laboratory. This has been achieved by bringing together some of this work from a number of departments and by starting new programmes of basic research. A number of these new research projects are already well under way and are producing results which may ultimately have a profound

effect on technology. The main impact of these new facilities, however, is likely to be through the body of scientists and engineers who will receive an advanced training in materials research through their association with the Interdisciplinary Laboratory.

The laboratory is staffed largely by faculty members drawn from a number of academic departments, at present mainly from physics, chemistry, electrical engineering and metallurgy, together with their graduate students. These are supported by technicians and engineering assistants. A small number of senior research staff holding appointments with the Division of Sponsored Research are also employed, together with an increasing number of young post-doctoral research staff continuing a research programme for two to three years after graduation. This form of further training has been growing in importance in the physical sciences and is now also becoming more common in engineering research. The laboratory is therefore largely an academic one, the director, Prof. R. A. Smith, C.B.E., F.R.S., being also a professor in the Physics Department. The director is supported by a steering committee, of which he is chairman, consisting of the deans of science and engineering and a number of senior faculty members.

The laboratory building was designed by the architectural firm Skidmore, Owings and Merrill of Chicago and has some novel features. It is a ferro-concrete structure built on five floors, giving a gross area of about 150,000 square feet. Since the building is joined to the main building of the Institute and forms a new north façade, the architects were faced with the problem of providing a functional and modern building which would fit in with the severely 'classical' form of the existing building. In this they have been successful. The new building is pleasing, yet distinctly modern, in appearance and in function. The design of the building is based on the concept of central vertical service cores around which the individual laboratories are arranged in groups of six on each floor. Each vertical shaft has cross-section 9 ft. \times 14 ft. and carries supply lines for hot and cold water, drains, various kinds of gas and compressed air, exhaust ducts for fume cupboards, heat canopies, etc. The laboratories are arranged in a double line on each side of the central plane of the building, though in a few instances particularly large laboratories are made by joining two so as to have twice the normal width. The access corridors run along the whole length of the building and on each of the long sides between them and the outside walls is a generous provision of offices and small conference rooms. The laboratories have no windows on to the corridors and are dependent entirely on the air-conditioning system for ventilation and on artificial lighting. The offices, on the other hand, have large windows forming a significant part of the outer walls. The provision of offices is such that all staff have office space in daylight, in general shared, except for senior faculty members. Light services are carried above false ceilings in the corridors. This design dictated full air-conditioning for the entire building which is supplied by means of a forced-flow air system through heat exchangers fed by steam brought in from the outside for heating and through installed chillers for cooling.

Many of the laboratories were designed with known needs in mind, but have been made sufficiently flexible so as to accommodate changes of programme. Electric power enters each laboratory from the vertical service cores in a 3 in. \times 5 in. metal raceway at bench height having ample capacity to distribute many current outlets around the walls, and to give a great deal of versatility.

The windows of the building, which are set in heavy wooden frames, are each 8 ft. high and made of heat-absorbing glass. They are set back 2.5 ft. from the external columns of the building. This provides shading and gives a reduction of sun-glare from the large expanse of window glass. These windows are one of the distinctive

architectural features of the building and give it its dominant external characteristic, as will be seen from the photograph.

Before the official opening of the new building a symposium on "Materials Science and Engineering" was held on September 30 and on the morning of October 1. The symposium, under the chairmanship of Prof. R. A. Smith, supported as session chairmen by Prof. A. H. von Hippel and Prof. N. J. Grant, covered a wide variety of topics. Speakers were drawn from the wider community of the Massachusetts Institute of Technology including the Lincoln Laboratory and the National Magnet Laboratory.

The first session was given over to basic research in solid-state physics. Prof. G. B. Benedek discussed some fascinating experiments on the scattering of light by thermally generated acoustic waves in liquids and solids. Of particular interest were some new results on scattering from liquids near their critical point. These experiments depend on the availability of highly monochromatic light sources of considerable power and illustrate well the use of lasers as powerful tools in physics research. Prof. D. P. Shoemaker described the use of low-energy electron diffraction techniques in the study of the arrangement of atoms on the surfaces of crystals and emphasized the importance of such studies in helping to clarify such processes as heterogeneous catalysis, corrosion, passivation and epitaxial growth. Prof. C. G. Shull described the use of polarized beams in neutron diffraction studies of ferromagnetic crystals particularly in determining the distribution of magnetization throughout the unit cell in such crystals. He also described some new experiments on the scattering of neutrons by type II superconductors, which show effects due to electron spin pairing and field penetration below the superconducting transition temperature. Prof. B. L. Averbach then showed how spin correlations have been determined above the critical temperature by studies of diffuse neutron scattering in single crystals of iron and MnO.

The second session opened with a review by Prof. J. C. Slater of what can be done at present in explaining the properties of solids in terms of quantum theory. He dealt particularly with band structure, including the shape of the Fermi surface in metals, and with the interpretation of experiments on solids in the presence of magnetic fields. Prof. B. Lax, National Magnet Laboratory, discussed the use of high magnetic fields in such experiments including the observation of helicon and Alfvén waves in solid-state plasmas. He also considered the use of high fields in the study of such phenomena as magnetic breakdown and the role of open orbits in conduction in metals in a high magnetic field. This session also included discussion of research on materials of interest in electronics. Prof. G. W. Pratt described his recent theoretical investigations of the lead salts, PbS, PbSe and PbTe, and showed how much better understanding of the band structure of these materials is now possible through the inclusion of relativistic effects in the calculations. He was able to calculate the variation of band structure with pressure and to predict the possibility and range of tuning of lasers made from these materials by application of pressure. Dr. R. H. Rediker of Lincoln Laboratory discussed laser action in semiconductors and showed how PbSe laser diodes had been tuned through the range 8–22 μ by use of the pressure effect, in some recent experiments carried out in collaboration with Prof. W. Paul of Harvard University. He also reported that lasers made with all three salts, PbS, PbSe and PbTe, had been made to operate through the use of optical excitation.

The third session of the symposium opened with a discussion by Prof. Morris Cohen of the essential phenomena which underlie the flow and fracture strength of various types of crystals including metallic, ionic and covalent crystals. The contributions and limitations of

the theory of dislocations were considered and the rather greater attention now being given to such things as precipitation hardening was emphasized. Prof. W. D. Kingery then discussed the control of microstructure in ceramics and showed the great importance of investigations of such structure in interpreting measurements of diffusion coefficients and related quantities in such materials. He emphasized the need for careful preparation of materials in order to obtain reproducible results. Prof. H. C. Gatos described some new studies of the surfaces of semiconducting compounds such as InSb and underlined the importance of such studies in understanding chemical reactions which take place at the surfaces of such semiconductors. The symposium concluded with a discussion by Prof. John Wulff of the metallurgy of hard superconductors. This type of material is becoming of great technological interest and it is important to understand the part played by the effects of processing on microstructure and on impurity content. Interaction of oxygen has been shown to have a marked effect on the upper critical field, and combination of thermal

and mechanical treatment have been shown to have effects which in turn depend on the impurity concentration.

During the symposium a luncheon and a banquet were held. At the former Dr. William Shockley spoke on the contrast between the teaching of materials science when he was a graduate student as compared with what is now taught to students and on the importance of imaginative terminology, illustrating his point with such terms as 'hot electrons' and 'optical pumping'. At the banquet the principal speaker was Dr. Harold Brown, now secretary of the Air Force. Dr. Brown emphasized the vital importance of materials research in all areas of technical development whether military or civil, and showed that there is scarcely an advanced project not limited by failure of materials to meet the ever-increasing demands made of them. He also spoke of the importance of new ventures in the utilization and management of federal funds for research and of the opportunities and responsibilities which academic institutions assumed in participating in federal support.

THE WALTER AND ELIZA HALL INSTITUTE OF MEDICAL RESEARCH, MELBOURNE

Sir Macfarlane Burnet, O.M., F.R.S.

ON September 1, 1965, Sir Macfarlane Burnet retired from the directorship of the Walter and Eliza Hall Institute, Melbourne, a position he had held with increasing distinction for twenty-one years.

Frank Macfarlane Burnet was born at Traralgon, Victoria, in 1899, and graduated in medicine from the University of Melbourne in 1922. After a resident year at the Melbourne Hospital, Dr. Charles Kelloway, then the director of the Walter and Eliza Hall Institute, recognized Burnet's research potential and persuaded him to join the staff of the Institute. Thus, with the exception of two study periods in London, Burnet was associated with the Walter and Eliza Hall Institute for forty-one years.

Burnet's first interest was in bacteriophage virus multiplication, and his early studies on one-step growth curves and genetic mutations in phage remain classics to this day. Immunology soon joined virology as a primary interest, and in 1930 Burnet studied staphylococcal toxin and produced an effective toxoid.

A period of study at the National Institute of Health in London, under Henry Dale, proved a turning-point in Burnet's career. This was the time of the discovery of ways of growing the influenza virus. Burnet soon mastered and developed the Goodpasture technique of virus culture in the egg embryo and, over the next twenty years, used this model for an extensive investigation of influenza virus multiplication. Burnet collaborated with Gottschalk and Ada on biochemical aspects of viral multiplication, leading to the discovery that influenza was an RNA virus and to the identification of the viral enzyme neuraminidase.

Immunological theory was a continuing interest of Burnet's, and in 1948 he and Fenner proposed the 'self-marker' theory of antibody formation, with its prediction of the phenomenon of immunological tolerance. This monograph deeply influenced the work of Billingham, Brent and Medawar; when these workers made immunological tolerance an experimental fact, a new era of cellular immunology began. For their work on immunological tolerance, Burnet and Medawar shared the Nobel Prize for Medicine and Physiology in 1960.

In 1957 Burnet found that the field of virology no longer excited him so much as it had done in the past. He took a courageous decision: the whole of the work of

the Walter and Eliza Hall Institute was to be switched progressively to immunology. The next three years saw the emergence of the clonal selection theory of antibody formation, the single cell approach to immunology by Nossal and Lederberg, and the increasing analysis of clinical auto-immune mechanisms by Wood and Mackay.

It was typical of Burnet that his Nobel Lecture in Stockholm in 1960 contained not an analysis of past achievements but a major prediction for the future. Burnet predicted that the thymus would prove of crucial importance to the understanding of the immune process. He returned to Melbourne to study the thymus of auto-immune mice—the extraordinary New Zealand Black strain. He encouraged Metcalf to pursue his studies of thymic influence on lymphopoiesis and leukaemogenesis in the cancer research laboratories of the Walter and Eliza Hall Institute. The extraordinary impact that the work on the thymus, performed over the past four years, has had on immunobiology led to a very fitting culmination of Burnet's long period as director of the Walter and Eliza Hall Institute. To mark his retirement, the Ciba Foundation organized a symposium on "The Thymus: Experimental and Clinical Studies", which was held in Melbourne in late August.

Burnet's honours are almost too numerous to recount. He was elected a Fellow of the Royal Society in 1942, was awarded its Royal Medal in 1947 and the Society's highest honour, the Copley Medal, in 1958. He was a Foundation Fellow of the Australian Academy of Science, and was elected its president in 1965. Burnet was knighted in 1951, and in 1958 was received in audience by Her Majesty Queen Elizabeth II, who conferred on him the Order of Merit. In 1960 he shared the Nobel Prize with Prof. P. (now Sir Peter) Medawar. Over the years he has received numerous honorary doctorates and lectured widely on his work and theoretical ideas.

No one who is familiar with Burnet's boundless enthusiasm, amazing capacity for work, and intense dedication to the cause of science will be surprised to hear of his retirement plans. Apart from his important duties as president of the Australian Academy of Science, he has joined the interim council of Melbourne's third university, La Trobe University (see *Nature*, 208, 434; 1965) and has become chairman of the New Guinea Medical Research Advisory Committee of the Australian Government. He has also accepted a position

as Rowden-White Research Fellow in the Department of Microbiology of the University of Melbourne, and will continue to work actively on the pathology and genetics of auto-immunity in mice. He hopes to write at least two major text-books—a major thesis on modern immunological theory, and a more popular work. We can thus look forward to a continued flow of enlightened speculation and inspiration from Burnet's richly productive pen.

Prof. G. J. V. Nossal

PROF. G. J. V. NOSSAL, formerly deputy-director of the Walter and Eliza Hall Institute, has been appointed to succeed Sir Macfarlane Burnet as director. Prof. Nossal was educated at St. Aloysius College, Sydney, and the University of Sydney, where he graduated B.Sc. (Med.) 1952 in bacteriology, and M.B., B.S., 1954, with first-class honours and a University Medal. In 1957 he joined the staff of the Walter and Eliza Hall Institute, graduating Ph.D. in experimental medicine in 1959. In 1960–61 he was assistant professor in the Department of Genetics, Stanford University School of Medicine, and visiting professor of immunology, University of Michigan, in 1961. He then returned to the Walter and Eliza Hall Institute.

Since then, he has been a visiting scientist to various institutes, notably the Children's Cancer Research Foundation, Boston, in 1962, and Irvington House Institute, New York University, in 1964. Dr. Nossal went to the Walter and Eliza Hall Institute when the emphasis was switching from virus work to immunology. Under the stimulus of Burnet and also Prof. Joshua Lederberg, then a visiting professor, Nossal was the first to demonstrate that isolated lymphoid cells (plasma cells) could liberate antibody. In doubly immunized animals the great majority of cells produced one type of antibody only. He also made important contributions to the understanding of immunological tolerance, and while at Stanford University investigated in detail the kinetics of cellular proliferation in lymph nodes stimulated by antigen injection. He has since made significant contributions to the study of antigen distribution in lymph nodes, thus opening up an important field in the relationship of antigen to the induction of antibody formation. His reviews on immunological topics have played a major part in the development of important aspects of the genetic aspects of immunity. On succeeding Sir Macfarlane Burnet he was appointed professor of medical biology in the University of Melbourne.

OBITUARIES

Prof. T. P. Hilditch, C.B.E., F.R.S.

PROF. T. P. HILDITCH, professor of industrial chemistry in the University of Liverpool during 1926–51, who was mainly responsible during those years for the great advance in our knowledge of the chemical constitution of natural oils and fats, died at his home in Oxtou, Birkenhead, on August 9.

Thomas Percy Hilditch was born in London in 1886 and educated at Owen's School, Islington. He proceeded to University College, London, in 1904, where he graduated B.Sc. with first-class honours in chemistry. In 1908 he was awarded an 1851 Research Exhibition, which enabled him to work for two years at Jena under Prof. L. Knorr and for one year at Geneva under Prof. Ph. Guye. He returned to University College to continue research with Prof. S. Smiles. His major interests in these years were the aromatic sulphones, sulphonic acids, and the relationship between optical activity and unsaturation. In 1911 he was awarded the D.Sc. of the University of London. By the time he was twenty-five years old he had published some forty papers and his reputation as a brilliant organic chemist was well established.

In 1911 Hilditch joined Joseph Crosfield and Sons, Ltd., Warrington, as research chemist. Crosfield's had recently put into operation the first successful plant for the hydrogenation of oils and fats. The hydrogenation process and catalysts for it were the subjects of major investigations carried out by Hilditch during his fourteen years at Warrington. The results of these were published, in conjunction with E. F. Armstrong, in a series of papers in the *Proceedings of the Royal Society*. This was not by any means the only field of investigation in which Hilditch worked successfully at Crosfield's. During the First World War, for example, he was intimately connected with a Government project at Warrington for the industrial production of acetaldehyde and acetic acid from ethyl alcohol.

In 1925 Hilditch was appointed to the newly created Campbell Brown chair of industrial chemistry in the University of Liverpool, a post he held until his retirement in 1951. It is by the results of his work during that period that he will always be remembered.

Only a year before Hilditch went to Liverpool, E. F. Armstrong had entitled his presidential address to the Society of Chemical Industry "A Neglected Chapter of

Chemistry: Fats". Hilditch's and his students' work at Liverpool between 1925 and 1951 completely removed any justification for the title of Armstrong's address to be used again.

Hilditch always considered that oils and fats were a branch of organic chemistry, and it was with this attitude that he commenced and carried out his work so successfully. Little quantitative information was available in 1925 on the component fatty acids of natural oils and fats, and not any on the component glycerides. Furthermore, the techniques for obtaining these were, for the first, inadequate and, for the second, non-existent. By 1951 not only had Hilditch and his students experimentally obtained this information for many oils and fats, but their work had stimulated others all over the world to work in this field. His classic book, *The Chemical Constitution of Natural Fats*, in the fourth (1964) edition shows that we now know quantitatively the component fatty acids of some 1,450 fats and the component glycerides of about 100.

He always believed that there was a relationship between the component fatty acids and glycerides, and the order of the evolutionary development of the parent organisms from which the fats were derived. This relationship was the basis on which he wrote his classic book. However, even in 1964 he felt that gaps in our knowledge remained, particularly in the component glyceride field, but he anticipated that with the aid of recent techniques such as gas-liquid chromatography, controlled enzyme hydrolysis and thin-layer chromatography, these would be quickly filled.

The success of Hilditch's research school at Liverpool became known throughout the world, so that by his retirement he had had students from very many countries. Not only did he successfully conduct his own Department, but he was also a colleague valued by many others on the University staff, and his services to the general administration were greatly appreciated.

During his retirement Hilditch continued his activities and interest in his subject and wrote two further editions of *The Chemical Constitution of Natural Fats*, as well as for some years acting as consultant to two industrial firms. He wrote five other books during his lifetime, three of which had two or more editions. These were text-books on physical and organic chemistry, and

A Concise History of Chemistry, written in his early years, while the later ones were *Industrial Catalysis* and *Industrial Fats and Waxes*.

Hilditch was elected a Fellow of the Royal Society in 1952. He was also a Fellow of the Chemical Society and the Royal Institute of Chemistry, and a member of the Society of Chemical Industry: he served the last two Societies as a council member and as vice-president. Up to the end of his life he continued to give great service to their Liverpool sections, by whom he will be greatly missed.

Hilditch was frequently consulted by Government bodies, and for his services to the Colonial Products Research Council he was awarded the C.B.E. in 1952.

During his retirement he received many other honours. In 1962 the Lampitt Medal from the Society of Chemical Industry, in 1964 the Chevreul Medal from the Grouperment Technique Des Corps Gras, France, and this year the American Oil Chemists' Society held in his honour a special symposium on "Glycerides", and their North Central Group gave him the Alton E. Bailey Award. Unfortunately, Prof. Hilditch was unable to receive these last two personally.

At a first meeting with Hilditch, even in his younger days, one had the immediate impression of a highly disciplined man with authority and of a somewhat austere mien, but on longer acquaintance something would occur to produce that kindly smile by which all his old friends affectionately remember him. The affection in which he was held was evinced by the many visitors to his home, particularly old students, and the honour which they felt when in turn he visited them, as he frequently did.

Hilditch always put his energies first into the duties of his position at the time, whether as student, industrial research chemist, or professor, but he was not without outside interests. He delighted in working in his garden or watching a cricket match and for many years served All Saints Church, Oxtou, as churchwarden. It was at this church that the final tribute was paid to him in the presence of a large number of his former colleagues, students and friends.

His widow, who greatly helped him in his work, survives him, and also three married daughters of a previous marriage.

P. N. WILLIAMS

Prof. C. B. Purves

PROF. CLIFFORD B. PURVES, chairman of the Department of Chemistry, McGill University, Montreal, died on September 30. As E. B. Eddy professor of industrial and cellulose chemistry he was also head of the Wood Chemistry Division of the Pulp and Paper Research Institute of Canada.

He leaves a widow, three sons, and three daughters.

Although honours embarrassed him, Dr. Purves's distinction as an educator and scientist was recognized through the award of two honorary degrees, one from Lawrence College, Appleton, Wisconsin (1944), and the other from Windsor University, Windsor, Ontario (1964). In 1960 the Chemical Institute of Canada, of which he had been president in 1956-57, presented him with its medal for distinguished service to the sciences of chemistry and chemical engineering in Canada. The American Chemical Society, in 1963, honoured him with the Anselme Payen Award for his contributions to the field of wood chemistry.

Dr. Purves was a man of modesty, warmth, generosity, fairness and inflexible honesty. Though he never failed to remember important things, true to the character of a professor he was absent-minded about trivia and often made his absent-mindedness the butt of his own wit. His sense of humour was strong; he had a large fund of anecdotes, always apt to the occasion, and, unlike many professors, he never ruined their point in the telling.

His strongest personal characteristic was concern. He was always concerned about each of his colleagues and students as individuals and, however busy he may have been, he never turned away a caller who might be troubled by a problem, personal or scientific. He always helped to the utmost of his power and probably felt his deepest frustrations on those occasions when his help was to no avail.

His concern extended far beyond his immediate colleagues to the profession of chemistry in general. His active participation in the Corporation of Professional Chemists of Quebec (he was its president in 1964) arose from his feeling of the need to strengthen the position of chemists as professionals.

Outside the realm of chemistry, Dr. Purves had other concerns. In his Convocation Address at the University of Windsor he spoke fervently of the need for educators, in their anxiety to cater for the demands of college-oriented youngsters of IQ 110 and higher, who constitute only 20-30 per cent of the general population, not to overlook the plight of the 20 per cent of IQ less than 80. He felt that in an increasingly technological society the lives of these latter people were becoming more and more aimless, and devoid of satisfactions.

In his Anselme Payen Award Lecture in 1963, Dr. Purves had also spoken of education. He felt that the greatest single deficiency of modern primary education in North America was its failure to teach elementary arithmetic, and he held up the Scottish education system as a model to be followed.

Born and educated in Scotland, Dr. Purves went to Canada in 1943 to succeed Prof. Harold Hibbert on the latter's retirement from the chair of industrial and cellulose chemistry. He arrived well prepared, having obtained his doctorate in 1929 in the field of carbohydrate chemistry under Sir James Irvine. During 1926-29 he had also worked as a Commonwealth Fund Fellow attached to the Polarimetric Division of the U.S. Bureau of Standards, in Washington, D.C., where C. S. Hudson had been his chief.

After two more years in Scotland, Dr. Purves moved to the United States in 1931, and became a research associate at the Chemical Foundation of New York (now the U.S. National Institutes of Health). During 1936-43 he was an associate professor of organic chemistry in the Massachusetts Institute of Technology.

At McGill, he built a strong research group, and continued his investigations of the chemistry of carbohydrates. A large part of his work was directed at the location of substituents in such cellulose derivatives as the acetates, xanthates and nitrates (see *Chemistry in Canada*, 25-29; December 1960). During this period he also began to interest himself in the lignin component of wood, and in 1947 published a method for the isolation of lignin by the mild oxidation of carbohydrates with potassium periodate (Ritchie and Purves, *Pulp and Paper Mag. Canada*, 48, No. 12, 74; 1947; Wald, Ritchie and Purves, *J. Amer. Chem. Soc.*, 69, 1371; 1947). This isolated lignin formed the basis of much subsequent work on the mechanisms of reactions related to the processes of the pulp and paper industry.

At McGill alone, more than a hundred students received their doctorate degrees under the tutelage of Dr. Purves. Many of them have now themselves achieved prominence in universities, government and industry.

Dr. Purves assumed the chairmanship of the Department of Chemistry in 1961, and under his administration the Department grew in the number and quality of its staff. But his chief task during the past four years was to supervise the planning and construction of the new Chemistry Building, named in memory of his long-time colleague, Prof. Otto Maass. That building now stands as a memorial to both of them.

HENRY I. BOLKER

NEWS and VIEWS

The Editor of NATURE

It is with deep regret that we announce the sudden death, on November 15, of L. J. F. Brimble, editor of *Nature*.

Jack Brimble and *Nature* have been so closely associated for so many years that we find it impossible as we now go to press to assess the loss to the journal and to the world of science.

An appreciation will appear next week.

The National Physical Laboratory:

Sir Gordon Sutherland, F.R.S.

At the end of October 1964 Sir Gordon Sutherland resigned from the directorship of the National Physical Laboratory to become Master of Emmanuel College, Cambridge. He joined the Laboratory in 1956 from the University of Michigan, where he had been professor of physics and director of the Biophysics Research Centre since 1949. His earlier work at Cambridge had brought him recognition as a leading authority on infra-red spectroscopy. As director of the National Physical Laboratory, Sir Gordon was responsible for many important developments in the work and facilities of the Laboratory. In 1958 he reorganized part of its divisional structure on a more functional basis, concentrating the metrological activities into the Applied Physics, Light and Standards Divisions and creating the Basic Physics Division to pioneer developments in molecular physics which were likely to have potential importance to industry. New buildings and facilities for the Ship Division were opened at Feltham by the Duke of Edinburgh in 1959, a new laboratory with special equipment for the mechanical working of refractory metals was provided for the Metallurgy Division in 1963, and the Basic Physics and Autonomics Divisions occupied new buildings in 1964. Glazebrook Hall, a former wind-tunnel laboratory reconstructed as a conference and social centre with catering facilities for the staff and visitors and including a lecture theatre seating 380, was opened in 1961; its name commemorates the first director of the Laboratory. A Van de Graaf accelerator and a *KDF 9* computer, respectively, were added to the facilities of the Applied Physics and Mathematics Divisions, and new equipment was installed for the work of the Aerodynamics Division on supersonic flight and industrial aerodynamics. During the period under review the total staff increased from 1,080 to 1,460, and the number of scientific officers, including Research Fellows, rose from 155 to 255. Sir Gordon was especially interested and successful in fostering contacts with the universities which were of mutual benefit, leading on one hand, for example, to better success in the recruitment of highly qualified graduates to the National Physical Laboratory, and, on the other, to a considerable expansion in the number and value of research contracts placed by the Laboratory with universities. The announcement of the award of his knighthood was made in the Queen's Birthday Honours List of 1960.

Dr. J. V. Dunworth, C.B.E.

DR. J. V. DUNWORTH has been appointed director of the National Physical Laboratory in succession to Sir Gordon Sutherland. Dr. Dunworth was born in Manchester and educated at Manchester Grammar School and Clare College, Cambridge, where he graduated with first-class honours in 1937. In the same year he joined Lord Rutherford's nuclear physics research team at the Cavendish Laboratory, and was later elected a Fellow of Trinity College, Cambridge. During the Second World War he

was a member of Sir John Cockcroft's team working on radar, and in 1944 he was seconded to the National Research Council of Canada, again with Sir John Cockcroft, to work on the development of atomic energy. At the end of the War, Dr. Dunworth returned to the University of Cambridge as a lecturer in physics. In 1947 he became a member of the staff of the Atomic Energy Research Establishment at Harwell, where in due course he became head of the Reactor Division. He was alternate United Kingdom member on the Organizing Committee of the United Nations Atoms for Peace Conferences held in Geneva in 1955 and 1958. Dr. Dunworth was appointed deputy director of the National Physical Laboratory in 1962 and has been acting as director since the resignation of Sir Gordon Sutherland in 1964. During 1965 he was responsible for implementing the decision to merge the National Chemical Laboratory into the National Physical Laboratory. He is president of the British Nuclear Energy Society, a member of the Council of the Institute of Physics and the Physical Society, and a member of the Institution of Electrical Engineers. He was elected a Fellow of the American Nuclear Society in 1960. Dr. Dunworth was appointed a C.B.E. in 1955.

It has also been decided by the Ministry of Technology to replace the Executive Committee of the National Physical Laboratory by a smaller Steering Committee. The first chairman of the new Committee will be Prof. B. H. Flowers, Langworthy professor of physics in the University of Manchester.

Electronic Engineering in the University of Hull:

Prof. D. A. Bell

IN appointing Prof. D. A. Bell to the newly established chair of electronic engineering, the University of Hull has added to its staff an engineer of international reputation with a wide and varied range of interests. Prior to his appointment, Prof. Bell was visiting professor of telecommunications at McGill University. Prof. Bell is perhaps best known for his work on noise, and his many contributions to the investigation of this subject have crystallized in his book, *Electrical Noise*. His knowledge of communications is also shown by many papers, and the titles of his other books—*Information Theory and its Engineering Applications*, *Statistical Methods in Electrical Engineering* and *Intelligent Machines*—show not only some of his interests, but also his constant endeavour to relate theoretical developments to engineering realities and his deep concern with the social consequences of engineering progress. He has always been anxious to work and study with social scientists and has long argued in favour of the inclusion of social science in the engineering curriculum. But his interest in education has not been limited to the universities, nor his knowledge of science to the physical sciences and the technologies based on them. Indeed, his outstanding characteristic is a scientific curiosity, to satisfy which he has worked at many problems in many fields and taken part in many controversies. His new colleagues will find him stimulating and vigorous and can rely on him not only to lead in his special field, but also to take an active part in the whole life of the University.

A. Harden (1865–1940)

BORN in Manchester on October 12 a century ago, Arthur Harden was first noted as an inspired lecturer and demonstrator at Owen's College, where he collaborated with Henry Roscoe on the writing of text-books. Harden graduated at Erlangen in 1888, spent nine years at

Manchester, and in 1897 took a post at the Jenner Institute of Preventive Medicine (which later became the Lister Institute). There he began his fruitful investigations of fermentation, and in particular of the yeast juices first prepared by Buchner. Although when kept warm the enzymes from yeast liquefied cell walls while the autolysed liquid still contained zymase, it was expected that, on heating, the enzymes would be destroyed. Harden, however, showed that boiled fluid or extract could increase fermentation due to the presence of a 'co-enzyme' containing phosphates: on adding potassium phosphate a vigorous fermentation set in. He was thus able to show how cell-free juice could be separated into co-zymase and apo-zymase. From this he developed the concept of ferment and co-ferment. He went on to show the relation between a hexose and phosphate—the enzyme reacting with phosphate being named 'phosphatase'—and discovered several ester-like 'sugar phosphates'. Apart from directing the biochemical division of the Lister Institute and holding a chair at London, Harden edited the *Biochemical Journal* and wrote many text-books. He was awarded the Davy Medal and shared the Nobel Prize with Euler-Chelpin, who carried on Harden's work on heat-stable co-enzymes and purified the co-enzyme of zymase.

Science in France

THE October–November 1964 issue of *Nouvelle Frontière* (No. 8) is of exceptional interest for a series of articles on the politics of science. G. Palewski writes on science and national independence; A. Lebarthe on a crusade for science; and F. Le Lionnais on the pattern of research. The organization of research in France is described by P. Frédet, and P. Piganiol writes on international scientific co-operation. Under the title "Research and Power", F. Maintenon discusses the duel between the United States and the U.S.S.R. P. Cognard deals with research and planning, and R. Goussault with manpower problems under the title "Investment in Man", while P. Aigrin deals with research and defence. There are also short articles on nuclear research, space research and research in biology and in electronics. Some problems of scientific policy are also considered in an article in *Le Progrès Scientifique* for May 1965 (No. 84), the preceding issue of which (No. 83, April 1965) is devoted mainly to a review of the situation and perspectives of biological and medical research in France, but includes also the text of a survey of biological and medical research in Europe by R. P. Grant, C. P. Huttner and C. C. Metzner, published in *Science* for October 23, 1964.

The British Glass Industry Research Association

THE tenth annual report of the British Glass Industry Research Association has recently been published (Pp. 42. Sheffield: The British Glass Industry Research Association, 1965). It records some important economic and technical developments for the year under review, not the least of which is the materially improved financial position of the Association, due to substantial sums of money emanating from the Department of Scientific and Industrial Research, the Ministry of Aviation, and the Electricity Council. The latter two sponsor special research projects: the former on the mechanism of strengthening of glass, the latter on investigating ways of facilitating the introduction of electric melting. On the technical side, the chief subjects considered in the report of the director of research, Dr. R. G. Newton, are: improvement of furnace life; heat utilization in furnaces; improvements in methods of founding glass; investigation of thermal conditions during glass-forming operations; improved strength in glass and glass articles; analysis of glasses and raw materials; and service behaviour of glass articles. One research achievement is emphasized in this report; this concerns the mechanism of upward-drilling

of refractories which has now been elucidated so convincingly that a ciné-film has been prepared to show exactly how it takes place in furnaces; this subject is described in some detail under the heading "Improvement of Furnace Life" in the director's report. The Association continues to maintain its valuable information service and, besides research, its miscellaneous work includes some consultative testing, testing of safety glass, surveys of lighting conditions in factories, and statistical analyses.

The Wildfowl Trust

THE annual report of the Wildfowl Trust for 1963–64 is a record of remarkable growth and success (Edited by Hugh Boyd. Pp. 136+32 photographs. Illustrated by Peter Scott. Slimbridge, Gloucestershire: The Wildfowl Trust, 1965). In four years the number of visitors has increased by 50 per cent. Finances are satisfactory, and the facilities for research continue to improve and increase in extent. The number of imaginative ventures to further the aims of the Trust increases each year, and, as an example, the report describes the identification competition for schools. This was held at the New Grounds on March 7 in bitterly cold weather. Sixty-four boys and girls from sixteen schools took part. Leighton Park again entered several strong teams and had three teams in the first five places in the Senior Competition; their A team won the first prize from Monmouth, thus reversing the previous year's result. In the middle age-group a team from Acklam Hall, who had travelled 260 miles from Middlesbrough, came first, with Winchester second. The junior prize was won by Gloucester Girls' High School by one point from Beaudesert Park. Besides full details of the collections, the report describes research and conservation initiated and carried out by members of the staff. It also contains articles by distinguished contributors on research and conservation in various countries overseas. The photographs and drawings are of the usual high standard, although, perhaps, Peter Scott has excelled all his former efforts with his coloured cover drawing; it deserves separate publication.

Careers with Instruments

Careers with Instruments is a pamphlet prepared by the Society of Instrument Technology and is, in fact, a guide to both school-leavers and graduates who may be considering a working life in the fields of measurement, automatic control, data handling and computation, all implying training and competence in the use of modern instruments (Pp. 24. Society of Instrument Technology, 20 Peel Street, London, W.E, April 1965. 2s. 6d.). The underlying theme of this pamphlet is that measurement and control serve and are served by all sciences and technologies; in effect, there is a two-way relationship between such disciplines as physics, mathematics, chemistry, electronics, nucleonics, chemical-, civil-, electrical-, mechanical- and production-engineering, also medicine, and measurement and control. The training pattern and prospects in this vocation are clearly set out and described, whether the starting-point be a secondary modern school, grammar school, or apprenticeship in the industry; it takes care of advancement via colleges of further education, technical colleges, colleges of advanced technology, and university qualifications. Thus are fashioned craftsmen, technicians, or persons capable of filling responsible technical posts, and so on, subject to acquisition of City and Guild Final Certificate, Higher National Certificate or Diploma, or institutional recognition, whichever best fits the particular course of higher education chosen by the individual until he or she achieves his or her ultimate goal. The instrument world is, at the present time, well co-ordinated in Britain by such organizations as the Worshipful Company of Scientific Instrument Makers; the Society of Instrument Technology; various associations of manufacturers, such as the British Industrial Measuring and Control

Apparatus Manufacturers' Association, the Scientific Instrument Manufacturers' Association, the Scientific Instrument Research Association, and the United Kingdom Automation Council. The work of the British Standards Institution, with its many standards and excellent codes of practice, conceived and executed in close co-operation with these various bodies, is a vital part of this closely knit organization, and is rightly acknowledged in this informative publication.

Cerebrovascular Accidents

THE booklet entitled *Cerebrovascular Accidents as a Public Health Problem—Selected Recent Abstracts II*, is the second of two publications on this important subject which are issued free from the School of Hygiene and Public Health, Johns Hopkins University (Pp. 64. Baltimore, Md.: Research in Public Health Administration Project, School of Hygiene and Public Health, Johns Hopkins University, 1965). It provides abstracts of recent papers by numerous authors on this disease and on problems related to it. After an introduction by Prof. C. M. Wylie, successive chapters deal with problems of diagnosis, epidemiology and statistics, preventive aspects, and medical and surgical care. The main aim of the booklet is to help readers to find original papers which they may have overlooked, and both *Abstracts I* and *II* should be valuable to everyone who is interested in advances in knowledge of these afflictions, or who is in any way associated with their practical care. Publication of the booklet has been financed by a grant from the W. K. Kellogg Foundation.

Aquatic Microbiology Group

A NUMBER of workers engaged in various fields of aquatic microbiology have for some time felt that it would be well worth while to call into being an informal aquatic microbiologists group. Such a group would be useful for the interchange of ideas and for a discussion of the problems encountered in this field. The autumn meeting of the Society for General Microbiology held in Aberdeen, on September 16–18, included a symposium on marine microbiology, and afforded an obvious opportunity to convene such a group. Accordingly, the group met for the first time at Torry Research Station, with Dr. Lucas, director of the Marine Laboratory of the Department of Agriculture and Fisheries for Scotland, in the chair. The meeting was entirely informal and was concerned more with work in progress, or with problems facing workers in this field, than with the accounts of completed work which are presented at the familiar formal scientific meeting. The first discussion was concerned with sea-water as a culture medium, and reference was made particularly to the suspended matter found in natural waters, which microbiologists usually remove when making their media. It was suggested that by so doing they changed the physical and chemical environment sufficiently to prevent some organisms from growing, and that by leaving the suspended matter in the medium it may be possible to culture certain micro-organisms that cannot, at the moment, be cultured by traditional techniques. The second discussion dealt with the 'dark growth' of certain phototrophic algae which also have the ability to grow heterotrophically in the dark. Much of the discussion was concerned with the interpretation of saturation constants and doubling times found for a number of algae and bacteria under various experimental conditions. These suggest that in the natural environment the bacteria would soon outstrip the algae in the utilization of the available nutrients. Possible mechanisms to explain these phenomena were put forward and examined. The third session was devoted to an account of the work, now in progress in various laboratories, on the bactericidal effect of light on *Escherichia coli* in sea-water. This led to a more general discussion of the effects of light in the

visible range of bacteria, and on the possible protective effect of carotenoid pigments. At the end of the discussion it was decided that further meetings of a similar type should be convened, the first to be held in about a year.

Fertilizer Corporation of India, Ltd.

THE Planning and Development Division of the Fertilizer Corporation of India, Ltd., publishes a quarterly bulletin entitled *Technology*, which is concerned with both academic and practical problems in the expanding field of fertilizer production and use. The contents of a recent issue indicate the scope of this journal (*Technology*, 2, No. 1; January–March 1965. Pp. 69, including separate subject index, Vol. 1, January–December 1964. Fertilizer Corporation of India, Ltd., Sindri, Bihar). The chief subjects discussed are: X-ray study of calcium ammonium nitrate, by S. K. Ghosh, V. K. Srinivasa and B. K. Banerjee; physical investigation of calcium ammonium nitrate, by S. Mukherjee, M. Samaddar and H. Roy; removal of nitrogen from fertilizer factory effluent by biochemical nitrification and denitrification, by A. C. Das, J. A. Khan and B. K. Dutta; trivalent arsenic compound as an inhibitor of corrosion of stainless steel in sulphuric acid, by A. K. Roy and K. M. Verma; extraction and estimation of humic and fulvic acids from soil and their fractionation by paper chromatography, by A. Sinha and R. N. Shukla; use of air from a nitric acid turbo-compressor for de-riming cold boxes in air-liquefaction units of an ammonia plant, by B. S. Kalia and C. L. Kaul; bulk blending and compatibility of fertilizers, by S. Varma; and reprography, by M. R. Roy. The subjects of short communications range from solubility of arsenic trioxide in aqueous ammonia at 40° and 50° C, desensitizers for ammonium nitrate, determination of total pyridines and quinolines in ammoniacal liquor by ultra-violet spectrophotometry, to testing of gas-mask canisters. Other features of this bulletin are technical digests, notes, news and statistics.

Organo-mineral Complex in Soils

THE complex of mineral and organic matter in soils has been intensively investigated both by chemists and by biologists. The problem presents great difficulties, since the organic matter is of complex constitution and the surfaces of the mineral matter vary from those of relatively well-recognized micro-crystalline clay minerals to those of amorphous oxides and hydroxides. A liberally documented review of present knowledge, entitled 'Interaction between Clays and Organic Compounds in Soils'. Part 1: 'Mechanisms of Interaction between Clays and Defined Organic Compounds', by D. J. Greenland, is presented in *Soils and Fertilizers* (28, No. 5, 415; 1965). Free organic material may be separated from weakly bonded material by flotation techniques in liquids of suitable density (1.8–2.0) following satisfactory dispersion. Except in very sandy soils, most of the total organic matter is bonded with inorganic material, the uncombined fraction being in an early stage of decomposition—the bulk of humic acids, for example, seems to be present in the complex. It would also appear that the clay-size mineral matter is mainly associated with the complex, while sand and silt are mainly 'free'. The forces concerned in the interaction may be Coulombic attractions, or Van der Waals forces, but there may be a large number of major and minor interactions between different parts of the surface of the mineral and the organic molecule. The relative importance of the various processes has been investigated by measuring the adsorption of well-defined organic compounds by montmorillonite, clays with mica-type lattices, kaolinite, and oxides. In general, organic compounds of molecular weight less than 150 are not adsorbed unless they can take part in ion-exchange, but larger molecules, with or without a charge, may compete

effectively with water molecules, and uncharged polymers are strongly adsorbed.

Carbon and Graphite Group

A CARBON and Graphite Group has been created by the Institute of Physics and the Physical Society. The aim of the new Group is to provide a meeting-ground for physicists who are interested in carbon and graphite materials, and to collaborate with similar groups in sister societies, in order to further the work of an informal group which has been meeting regularly in London. The meetings are expected to interest theoretical physicists and those working with these materials in industry, academic institutions and Government laboratories. Joint meetings with other societies on topics of common interest are also envisaged. Prof. A. R. Ubbelohde and Dr. G. S. Parry have been appointed chairman and honorary secretary, respectively, of the provisional Committee, and the remainder of the members who signed the request for the formation of the Group will be invited to serve on it. It is anticipated that the first elected Group Committee will be nominated and elected by the Group members in the summer of 1966. Further information regarding membership of the Institute and Society and of its Carbon and Graphite Group can be obtained on request from the Registrar, Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

The Emmie Clough Scholarship

THE Royal Horticultural Society has announced that it is offering a scholarship provided out of a bequest from the late Mrs. Emmie Clough, to enable a girl to take a course of training in horticulture which would otherwise be beyond her means. The scholarship, valued at £380 a year, will commence in September 1966. It will be open to women between the ages of eighteen and thirty, and will be tenable for two years at Waterperry Horticultural School, Nr. Wheatley, Oxford. Candidates will be required to have attained a standard of education which will permit them to take full advantage of the course of study, and should normally have completed or be prepared to undertake such periods of practical training in horticulture as may be considered necessary. Further

information can be obtained from the Secretary, Royal Horticultural Society, Vincent Square, London, S.W.1.

University News:

London

PROF. W. MORRIS-JONES, professor of political theory and institutions in the University of Durham, has been appointed director of the Institute of Commonwealth Studies and professor of commonwealth affairs from January 1. Dr. G. S. W. Organe has been appointed to the chair of anaesthetics, tenable at Westminster Medical School. The following readers have also been appointed: Dr. S. Rosenblat (theoretical mechanics, tenable at the Imperial College of Science and Technology); Dr. J. S. Tooms (applied geochemistry, tenable at the Imperial College of Science and Technology). The following titles have been conferred: *Professor*, Dr. H. Spencer (morbid anatomy, in respect of his post at St. Thomas's Hospital Medical School); Dr. J. W. Smith (chemistry, in respect of his post at Bedford College); *Reader*, Dr. T. J. Chandler (geography, in respect of his post at University College); Dr. J. R. May (bacteriology, in respect of his post at the Institute of Diseases of the Chest).

Announcements

MR. H. WILLIAMSON (Canada) has been appointed chairman of the Executive Council of the Commonwealth Agricultural Bureaux in succession to Mr. C. S. McMorris (Jamaica) as from January 1, 1966. Mr. J. A. Afari (Ghana) has been appointed vice-chairman, from the same date.

A SYMPOSIUM on "The Distribution and Biochemistry of Latex in Plants", organized by the Phytochemical Group, will be held in the School of Pharmacy, London, on January 6. Further information can be obtained from Mr. A. H. Williams, Research Station, Long Ashton, Bristol.

A MEETING on "Management Control and Computers", arranged by the Central London Productivity Association, in association with the British Productivity Council, will be held in London during December 9-10. Further information can be obtained from Mr. L. Fuller, Arthur Andersen and Co., St. Alphage House, 2 Fore Street, London, E.C.2.

ENZYME NOMENCLATURE

THE Commission of Editors of Biochemical Journals (J. T. Edsall (*president*), W. V. Thorpe (*secretary*), A. Dillmann, W. A. Engelhardt, Y. Raoul, E. C. Slater), appointed by the International Union of Biochemistry (IUB), wishes to direct attention to the recently published *Enzyme Nomenclature*¹, which is the report of the IUB Standing Committee on Enzymes.

The draft of this report was considered by a joint meeting of the Standing Committee and the IUB Commission of Editors of Biochemical Journals in Rome in February 1964. The version agreed to by that joint meeting was adopted by the Council of the IUB at its meeting in New York on July 27, 1964, and designated *Recommendations (1964) of the IUB on the Nomenclature and Classification of Enzymes*.

The report of the Standing Committee on Enzymes is based on the report of the IUB Commission on Enzymes², adopted by the General Assembly of the IUB in Moscow on August 16, 1961. The changes made by the Standing Committee in the report of the Commission on Enzymes are of four types: (a) additions of new enzymes, and, where necessary, new sub-groups to accommodate them; (b) correction of definite errors in the first edition; (c) changes in the nomenclature itself to meet criticisms which had been put forward; (d) addition of systematic names in some cases where the original Commission put forward only trivial names.

The chapter on the nomenclature of the cytochromes was revised by a special committee set up for this purpose. The chapter in the new report includes proposals for the nomenclature of haem compounds and haemoproteins in general.

Since the publication of the Report of the Commission on Enzymes in 1961, many of its recommendations have been widely used in scientific journals and text-books. Most biochemical journals urge authors to follow most of the recommendations even if they do not insist on all. Some journals already require the procedure suggested in Chapter 6, p. 29, that when an enzyme is the main subject of a paper or abstract, its code number (preceded by the letters *EC*), systematic name and source should be given at its first mention; thereafter the trivial name may be used. Enzymes which are not the main subject of the paper or abstract should be identified at their first mention by their code numbers. When the paper deals with an enzyme which is not yet in the Enzyme Commission's list, the authors may introduce a new systematic name and/or a new trivial name, both formed only according to the recommended rules, but a number should be assigned only by the IUB.

An addition to the new report is the inclusion in the index of names which have been in frequent use but which are no longer recommended. It was often difficult to find in the old report the new name of an enzyme known to the reader only by its old name. Many enzymologists may note with regret that the name by which they have long known a favourite enzyme is printed in italics in the index, indicating that it is not recommended. For example, fumarase (*EC* 4.2.1.2) is replaced by fumarate hydratase as trivial name (systematic name, L-malate hydro-lyase). Those who are irritated by this change should perhaps pause to think how many students first coming across the name fumarase might legitimately think that it catalyses the hydrolytic splitting of fumaric acid. Those who shed muramidase-containing tears on reading the first report may now rejoice that the old name lysozyme (*EC* 3.2.1.17) has been restored, whereas *muramidase* is now relegated to the list of disapproved names.

The chapter on enzyme units has received only one alteration. In the first report a standard temperature of

25° C was suggested, but this is now changed to 30° C because of the ambient laboratory temperature prevailing in many countries. No biochemical journals insist on the use of the Enzyme Commission's unit (*U*) of enzyme activity (the amount which will catalyse the transformation of 1 μ mole of the substrate per min under standard conditions). However, this unit is to be strongly recommended and some journals suggest conversion of data in terms of the new unit when the paper has to be returned to the author for other revisions. The derived units specific activity (*U*/mg) and molecular activity (*U*/ μ mole enzyme) are also to be recommended. Where inconvenient numbers would otherwise be involved, terms such as milli-unit (*mU*), kilo-unit (*KU*) or, for those who specialize in small activities, nano-unit (*nU*) or pico-unit (*pU*).

The IUB Commission of Editors of Biochemical Journals would particularly like to direct the attention of authors to the recommendation that enzyme assays be based wherever possible on measurements of initial rates of reaction in order to avoid complications due, for example, to reversibility of reactions or to the formation of inhibitory products. Many papers are submitted in which kinetic parameters are calculated on the basis of data in which the initial rate was not measured. The substrate concentration should be, wherever possible, sufficient for saturation of the enzyme, so that the kinetics in the standard assay approach zero order. Where a distinctly sub-optimal concentration of substrate must be used, the Michaelis constant should be determined where feasible so that the observed rate may be converted into that which could be obtained on saturation with substrate.

The chapter on the symbols of enzyme kinetics is unchanged. The recommended symbols, *v* (velocity), *V* (*v* at infinite substrate concentration), *K_m* (Michaelis constant, that is, substrate concentration where *v* = *V*/2), *K_s* (substrate constant, that is, dissociation constant of the reaction *E* + *S* \rightleftharpoons *ES*), *K_i* (inhibition constant, that is, dissociation constant of the reaction *E* + *I* \rightleftharpoons *EI*), and *k* for rate constant are widely used. The recommended numbering of rate constants for enzyme systems involving consecutive steps, namely:

has not been widely adopted, and editors are still reluctant to request authors to make the extensive alterations to the typescript which would often be necessary.

The chapter on the classification and nomenclature of cytochromes has been completely rewritten. The term cytochromoid, introduced in the previous report to describe haemoproteins with haemoglobin-like structure and a reactivity with ligands which do not react with cytochrome *c*, has been set aside. It is now proposed that these non-haemochrome haemoproteins should be considered as variant *c*-type cytochromes. To indicate that a haem *c* prosthetic group is not in a haemochrome linkage, a dashed symbol, *c'*, is recommended. This chapter also defines a number of haem compounds and contains much useful information on the chemistry of these compounds and of haemoproteins. The individual cytochromes are now described in greater detail and some cytochromes appearing in the previous list have been dropped. Cytochromes *c₄* and *c₅* are now brought under cytochrome *c₂*. Cytochrome *f* is given the name cytochrome *c₆*, although no doubt it will continue to be called cytochrome *f* as well. Cytochrome *d₁* (*a₄*) and a number of *C* cytochromes have been dropped. Indeed, the capital letters, introduced in the first report to describe a cyto-

chrome at a certain stage of the investigation, have been dropped.

The chapter on the terminology of enzyme formation does not appear in the new report. Part of it (formation from precursors) has been added to the chapter on classification and nomenclature of enzymes.

The chapter on the nomenclature of the nicotinamide nucleotide co-enzymes is an abbreviated version of part of the chapter on the nomenclature of coenzymes in the first report. The sections on ubiquinone or coenzyme Q and on coenzyme A have been omitted, since these compounds have been considered by the IUPAC (International Union of Pure and Applied Chemistry)-IUB Joint Commission on Biochemical Nomenclature, which maintains close contacts with the IUB Commission of Editors of Biochemical Journals. Ubiquinone (coenzyme Q) has been considered in a report on the nomenclature of quinones with isoprenoid side-chains (see, for example, ref. 3). This report makes two alternative recommendations for the naming of ubiquinone (coenzyme Q), namely: (1) the name be ubiquinone-*n* and the abbreviation *Q_n*, where *n* is the number of isoprenoid units in the side-chain; (2) the name be ubiquinone *Q_n* and the abbreviation *Q_n*. No changes in the name coenzyme A (CoA, CoASH) are proposed.

One of the more controversial recommendations of the Enzyme Commission was the use of the name nicotinamide adenine dinucleotide (NAD) and nicotinamide-adenine dinucleotide phosphate (NADP) instead of DPN and TPN. Many criticisms were received by the Standing Committee on Enzymes. These received careful consideration, but the Committee decided that the original arguments as set out in Chapter 4 of the *Report of the Commission on Enzymes* were sufficient to warrant no interference being made with their decision.

The editorial boards of some biochemical journals have encountered strong opposition from their authors to the replacement of the DPN-TPN nomenclature. Although the IUB Commission of Editors of Biochemical Journals has endorsed the new nomenclature, two of the larger journals represented in the Commission have been unable to enforce it, and have permitted the two systems to stand side by side.

In the first report, the Commission on Enzymes recommended two alternative systems of designating the reduced forms of NAD and NADP acting as substrates for enzyme reactions. The two systems were formulated $\text{NAD}^+ \rightarrow \text{NADH} + \text{H}^+$, and $\text{NAD} \rightarrow \text{NADH}_2$. The latter formulation was used in the enzyme list. In the new report the two forms are referred to simply as 'NAD' and 'reduced NAD' in the enzyme names and in the chemical equations illustrating the reaction catalysed by the enzyme in question. On the other hand, the IUPAC-IUB Commission on Biochemical Nomenclature has recommended that the abbreviations NAD and NADP should be used only when the state of oxidation of the compounds need not be specified. The oxidized and reduced forms of the coenzymes should be designated by NAD^+ (NADP^+) and NADH (NADPH), respectively. These may be used in an equation as follows:

For this reason, some journals will permit and even prefer the designation of an enzyme such as EC 1.6.99.3 by NADH: (acceptor) oxidoreductase (systematic name) and NADH dehydrogenase (trivial name) rather than by the names reduced-NAD: (acceptor) oxidoreductase and reduced NAD dehydrogenase, respectively, which appear in the new report. This is in conformity with current practice.

Because of difficulties with indexing, the use of chemical formulae in enzyme names has been prohibited, for example, EC 1.11.1.6 (catalase), which was given the systematic name $\text{H}_2\text{O}_2 : \text{H}_2\text{O}_2$ oxidoreductase in the first edition, has now been changed to hydrogen-peroxide:

hydrogen-peroxide oxidoreductase. (Some journals may object to placing a hyphen between the two parts of a chemical name, which, according to the conventions of chemical nomenclature, do not have a hyphen in the English language.)

On the other hand, standard abbreviations for compounds of importance in biochemistry, as accepted by the IUPAC-IUB Commission on Biochemical Nomenclature, have been used in enzyme names, for example, ATPase (EC 3.6.1.3 and 3.6.1.8). Indeed, more use could possibly have been made of standard abbreviations, and editors will not object when these are used in enzyme names, for example, glutathione: hydrogen-peroxide oxidoreductase (EC 1.11.1.9) could be written GSH: hydrogen-peroxide oxidoreductase, and the systematic name of glutathione reductase (EC 1.6.4.2) can, in the opinion of the Commission of Editors, be legitimately written $\text{NAD(P)H} : \text{GSSG}$ oxidoreductase instead of the longer name, reduced $\text{NAD(P)} : \text{oxidized-glutathione oxidoreductase}$.

The new report repeats the statement of the first report that abbreviations for names of enzymes, for example, GDH, should be strongly discouraged. While the Commission of Editors endorses this statement, and many journals rigorously enforce the prohibition of abbreviations for the names of enzymes, it must be recognized that such abbreviations are widely used, especially in clinical chemistry. It may soon be necessary to rationalize and standardize this practice rather than to ban it.

The most important change in the enzyme list is the reclassification of hydrogenases (Group 1.12), oxygenases (Group 1.13) and hydroxylases (Group 1.14). Errors in the first list have been corrected and many new enzymes added. The list now contains 875 enzymes.

It is obvious that the further purification of enzymes and advances in our knowledge of the mechanism of reactions catalysed by specific enzymes may soon make the recommended nomenclature no longer acceptable in certain cases. The present basis of classification is functional because sufficient chemical knowledge is absent. When more becomes known about the nature of active sites and amino-acid sequences, a chemical classification may become possible.

It is also clear that not everyone will agree with the classification and nomenclature of all the 875 enzymes. Editors of biochemical journals will carefully and sympathetically consider reasoned requests by an author to depart from the recommended nomenclature, and will forward them to Prof. E. C. Webb, who has been designated by the Council of the IUB to assemble such comments. Indeed, the Standing Committee on Enzymes received and considered many criticisms from authors which were transmitted by the editorial boards of various biochemical journals. If the editorial board agrees with the arguments brought forward by an author, it will allow him to depart from the recommendations of the enzyme report. It would be desirable to state the reasons for this departure in the text of the paper or in a footnote.

It should be added, however, that the experience of editors is that many authors have not grasped the basis of the nomenclature recommended by the Commission on Enzymes, namely that an enzyme should be named according to the reaction which it catalyses. Since the specificity of enzymes is not absolute, some arbitrariness in naming the substrate is inevitable. The principles followed by the Commission on Enzymes in choosing between different possibilities are given in Rule 14, p. 32, of the new report. Since it appears that few authors are fully aware of the implications of this rule, it might be useful to consider it in more detail. The long-known enzyme succinate dehydrogenase (EC 1.3.99.1) is given the systematic name succinate: (acceptor) oxidoreductase, even though it also catalyses the oxidation of a number of α -monosubstituted succinates. On the other hand, alcohol dehydrogenase (EC 1.1.1.1) is named alcohol: NAD oxido-

reductase, because it acts on a wide range of alcohols. Lactate dehydrogenase (*EC* 1.1.1.27) is named L-lactate : NAD oxidoreductase, even though it reacts quite rapidly with NADP as well as with NAD. However, the most commonly occurring glutamate dehydrogenase (*EC* 1.4.1.3) is named L-glutamate:NAD(P) oxidoreductase (deaminating), because it reacts readily with both NAD and NADP (see Rule 16). The aldehyde dehydrogenases give special difficulties. No less than 18 are listed in Group 1.2.1 (with NAD or NADP as acceptor). Of these, 14 are named in terms of a specific hydrogen donor, while in the others the donor is given simply as aldehyde. This should not be taken to mean that the 14 are absolutely specific for a single aldehyde. Of the 18 enzymes, NAD is given as acceptor for 8, NADP for 6 and both nucleotides for 4.

There are many discrete enzymes, differing in amino-acid composition, physical properties and enzyme kinetics, all of which have to be named aldehyde : NAD oxidoreductase (*EC* 1.2.1.3). At present these must be distinguished by source, such as organism, tissue and cell component. The IUB Commission of Editors of Biochemical Journals has set up a sub-committee to consider the problems of nomenclature posed by recent research on the nature of isoenzymes and enzyme sub-units.

INTERNATIONAL COMMITTEE ON LABORATORY ANIMALS

THE International Committee on Laboratory Animals held its third international symposium at Dun Laoghaire, near Dublin, during September 6-17 under the general title, "The Husbandry of Laboratory Animals".* The Committee, while well known to those professionally engaged in laboratory animal science, appears to be largely unknown to the users of laboratory animals. It was, however, the users, who, acting through their international unions, set up the Committee. It seems appropriate, therefore, that a general report of the Committee and its work should be made to laboratory animal users on this occasion.

History. Ten years ago two independent initiatives towards an international organization were being made. One was by the International Union of Biological Sciences and the other by the Council for International Organizations for Medical Sciences working in association with Unesco. In December 1956 these organizations met and recommended the establishment of the International Committee on Laboratory Animals. The International Union of Physiological Sciences joined soon after, and the Committee was established as an inter-union committee; experts, who were heads of laboratory animal centres, were co-opted. Unesco provided most of the financial support and was represented on the Committee by an observer. Two other unions have since joined—the International Union against Cancer and the International Union of Biochemistry.

The growth of the Committee's activities was such that by 1961 a revised constitution was necessary. Laboratory animal centres or committees had been established in many countries to co-ordinate work in the field and act as information centres. It seemed important to associate these bodies with the International Committee. The Committee now consists of the union members and national representatives, numbering twenty-seven, coming from all parts of the world. The final authority rests with the governing body, which consists of all the union representatives together with an equal number of national representatives; the World Health Organization is represented by an observer. In effect this is an equal division between the users and the laboratory animal experts. The detailed work is done by an executive committee of individual experts.

The financial support from Unesco was only temporary and in 1962 it ended. The Committee is most grateful to Unesco. The World Health Organization has now undertaken to support the work of the Committee, and to that Organization also the Committee is deeply grateful.

Activities. Surveys of the production and utilization of laboratory animals have been carried out and published in relation to twenty-one countries. This has enabled the

problems to be assessed and has provided a strong stimulus to the development of national centres dealing with problems connected with laboratory animals. Another major factor in such development has been the visits, made under Committee auspices, of the officers and other experts to many countries to give advice on laboratory animal problems. Up to the present time this advice has been mainly concerned with the development of healthy supplies of small mammals. Similarly, other activities have been concentrated in this direction. Thus, efforts have been made to improve technician training, and notes on training courses have been published in the *International Committee on Laboratory Animals Bulletin* which is published twice a year. Scholarships have been awarded to a number of workers in the field, and this has enabled them to work for a time in one of the established centres, in this way helping the development of new centres elsewhere.

Two previous international symposia have been held on "Living Animal Material for Biological Research" and "The Problem of Laboratory Animal Disease". These, together with that just held, have provided a forum for the discussion of a range of scientific problems connected with the supply of healthy animals, in particular small mammals.

Besides the basic problems of improving the health, nutrition and handling of animals, two other general fields have always been on the Committee's programme. The first of these concerns more specialized questions related to the breeding of small mammals. This side of the work has included a bibliography (now taken over by the publishers of the *Zeitschrift für Versuchstierkunde*—Gustav Fischer Verlag, Jena, German Democratic Republic) and the preparation of lists of agreed definitions. These are slow steps towards the difficult task of designating primary type colony centres and listing the primary type colonies being maintained. The difficulty in this task lies in specifying strains in such a way that the designations have real meaning.

The Committee is one concerned with laboratory animals of all kinds and not simply small mammals. One of its early aims was to establish world lists of sources of laboratory animals, especially lower vertebrates and invertebrates. This aim has so far proved very difficult to achieve and, with the concentration of effort on standards of care in animal houses for small mammals, little has yet been done in this field. This has caused some concern, and the governing body has now put on record its hope that some advance in the non-mammalian field may take place in the next three years.

In all these fields of activity this international organization is primarily a channel of communication between national organizations, and the latter have, as one of their functions, the giving of information not only to those

* The proceedings are being published by Academic Press.

actively involved in laboratory animal care and production, but also to any user of experimental animals. In Great Britain the centre is the Laboratory Animals Centre (director, Mr. J. Bleby), Medical Research Council Laboratories, Carshalton, Surrey, and the national

representative on the International Committee is Dr F. J. C. Roe, Department of Experimental Pathology, Chester Beatty Research Institute, Institute of Cancer Research, Fulham Road, London, S.W.3.

J. A. B. GRAY

BASIC COMPONENT OF SOLAR RADIO EMISSION AT CENTIMETRE AND DECIMETRE WAVE-LENGTHS

By DR. M. K. DAS GUPTA and D. BASU

Institute of Radio Physics and Electronics, University of Calcutta

IT is now well established that at centi- and decimetre wave-lengths the solar radio emission, apart from the more rapidly varying features like bursts of various types, consists of: (1) a basic component remaining constant over a considerable period of time; (2) a slowly varying component showing a slow day-to-day variation in intensity. Of these two, the first is the radiation from the Sun when the disk is completely free from any active region while the slowly varying component is the excess radiation due to localized active zones on the disk. The method of separating the two components from the total solar flux was first introduced by Pawsey and Yabsley¹, who plotted the total flux against sunspot area and extrapolated the best-fitting line to the condition of zero area on the assumption that the radio flux depends on sunspots only. However, it is now confirmed² that the regions corresponding to sunspots continue to emit radio waves in cm- and dm-wave-lengths for a considerable period even after the visible sunspots have disappeared and also that these start emitting much earlier than the actual appearance of the sunspots. There are thus present on the solar disk, at any instant, some active regions that are strong sources of radio emission but are not at all associated with the then visible sunspots. As such, the basic component cannot be segregated from the total flux by taking into account sunspots alone.

Attempts were made independently by Allen³ and Covington and Harvey⁴ to determine the basic component with this new consideration in view. However, Allen's method seems to be too complicated and does not appear to be readily applicable from a practical point of view. Regarding the analysis by Covington and Harvey, on the other hand, the assumption that the contribution from radio regions not associated with sunspots is proportional to the number of sunspot groups is only a rough approximation. We were thus prompted to examine the aspect of the evaluation of the basic component of solar radio emission in relation to recent data.

As has already been mentioned, the slow day-to-day variations of the solar radio flux would be due to the presence of active regions, visible or invisible, on the solar disk. These variations exhibit roughly a 27-day period of recurrence which corresponds to the apparent period of rotation of the Sun about its vertical axis. It may, however, be mentioned in this connexion that such variations in the solar radio flux exist⁴ even at zero sunspot number condition which can thus be attributed to active regions other than those associated with sunspots. It is obvious that there will be no variation at all of the daily values of solar flux if the disk is free from any active radio region, and hence, so far as the basic component is concerned, the amplitude of such variation will be zero.

In our analysis we considered solar radio flux data at frequencies 1,000, 2,000, 2,800, 3,750 and 9,400 Mc/s. The daily values of the flux at each of these frequencies were plotted separately for the years 1958 (sunspot maximum) and 1964 (sunspot minimum). All these curves showed substantially similar variation for the individual

years and indicated pronounced maxima and minima following roughly the 27-day period. Fig. 1 shows such plots for the frequency 3,750 Mc/s for the years 1958 and 1964 as well as 1961. An additional striking feature exhibited by the daily mean flux curves is that the pronounced maximum-to-minimum amplitude of this variation seems to change rather systematically with the mean value of the flux. Thus the amplitude is highest for 1958 when the mean flux is also maximum, and it is lowest for 1964 when the mean flux is minimum, while for 1961 the condition is intermediate between the two. We were thus led to examine the matter in some detail. For any frequency we determined the maximum-to-minimum amplitude of variation of the daily mean flux corresponding to each of the 27-day cycles (henceforth called variation amplitude or VA) individually for both the years. The mean values of the solar radio flux for each of the periods corresponding to these cycles were also determined. For any particular frequency and for any particular year, we thus obtained a set of VAs and the corresponding values of mean solar radio flux. These flux values were plotted against corresponding variation amplitudes. Fig. 2 shows the plots for the frequencies 1,000, 2,000, 3,750 and 9,400 Mc/s separately for 1958 and for 1964. The linear relationship between the solar flux and the amplitude of variation is at once evident. On extrapolating to zero value of VA the best-fitting line is found to cut the flux

Fig. 1. Plots showing the variation with time of the daily mean solar radio flux at 3,750 Mc/s for 1958, 1961 and 1964

Fig. 2. Plots showing the linear relationship between the mean values of solar radio flux and the amplitudes of variation of the flux for periods corresponding to the so-called 27-day cycles at frequencies 1,000, 2,000, 3,750 and 9,400 Mc/s for the years 1958 (O) and 1964 (x). The upper scale in each case indicates the values for 1958, while the lower one indicates those for 1964.

axis with a positive intercept. This value of the solar flux, corresponding to zero value of VA, can thus be attributed to the basic component of solar radio emission at that particular frequency. The total solar flux at any of these frequencies can thus be represented by:

$$F = F_0 + KV$$

where F is the total flux, F_0 is the basic component, V is the amplitude of variation of flux corresponding to the 27-day cycle and K is a constant. The basic component was similarly calculated for all the five frequencies separately for both the years. It should, however, be noted that in determining the 27-day cycles sufficient care was taken to be sure that each of these exhibits pronounced maxima and minima very clearly. Any ambiguous cycle was rejected altogether from considerations. Further, if the same value of VA appeared more than once in a year, the average value of the corresponding mean solar fluxes was taken. This method of determining the basic component would thus eliminate the effect of all sorts of active regions on the solar disk, visible or invisible. It should be noted in this connexion that the present method of evaluating the basic component will be possible only for the frequency range 470–29,000 Mc/s for which the characteristic 27-day variations in received solar radio flux exist, as we have shown⁴.

Table 1 shows the values of the basic component, F_0 , of solar radio emission at different frequencies individually for the years 1958 and 1964, corresponding to the maximum and minimum periods of solar activity respectively, and also the ratios $(F_0)_{\max}/(F_0)_{\min}$ (designated henceforth as ρ).

The flux values at different wave-lengths of the basic component F_0 , converted to corresponding equivalent black-body temperatures, have been plotted in Fig. 3 both for sunspot maximum and minimum years. For comparison, the continuous curve representing the experimentally obtained values compiled by Ellison⁵ has also been shown. It is quite evident from the $(F_0)_{\max}$ and $(F_0)_{\min}$ plots that the basic component varies in course of a solar cycle. The factor ρ by which it changes from maximum to minimum years is found to depend on frequency as has been shown in Fig. 4. The variation

Table 1. BASIC COMPONENT OF SOLAR RADIO EMISSION AT DIFFERENT FREQUENCIES IN JANSKYS FOR SUNSPOT MAXIMUM AND SUNSPOT MINIMUM YEARS

	1,000 Mc/s	2,000 Mc/s	2,800 Mc/s	3,750 Mc/s	9,400 Mc/s
1958 (max)	110.3	115.3	172.2	163.8	286.0
1964 (min)	31.4	42.7	67.7	83.2	238.6
ρ	3.5	2.7	2.5	2.0	1.2

appears to be negligible at wave-lengths less than 3 cm and seems to increase with increasing wave-length. It appears that ρ is unity at frequencies above 10,000 Mc/s (10,810 Mc/s to be exact), which implies that the radio flux of the quiet sun originating at the base of the chromosphere, as also from the photosphere, undergoes no change in intensity in course of a solar cycle. This corroborates the results obtained earlier by Van de Hulst⁶ and also by Christiansen and Hindmann⁷.

It should, however, be noted here that the factor ρ obtained at dm-wave-lengths is slightly greater than that proposed by Van de Hulst from considerations of a change in the coronal electron density determined from brightness variation. This might possibly be due to the fact that the activity of the present solar cycle, for which this analysis has been made, was far more prominent than the earlier ones. As such, the maximum-to-minimum variation in the coronal electron density, and hence that in the radio flux from the quiet sun, is possibly greater than that observed by previous workers.

As regards the metre wave region, however, the predictions of Van de Hulst and also the investigations of Christiansen and Hindmann suggest no change in the basic component from sunspot maximum to minimum conditions. Lack of continuous data at frequencies less

Fig. 3. Apparent temperatures of the quiet sun at different wave-lengths obtained from the present analysis for the years 1958 (O) and 1964 (x). The solid line indicates the spectrum determined experimentally by interferometer technique.

Fig. 4. Curve showing the variation with frequency of the ratio of basic component at sunspot maximum to that at sunspot minimum.

than 1,000 Mc/s did not permit us to extend the present analysis at higher wave-lengths. However, the spectra of the basic component (Fig. 3) both at sunspot maximum and minimum years seem to follow appreciably the experimental curve, and hence it can perhaps be logically assumed that at higher wave-lengths, where the curve becomes asymptotic, $(F_0)_{\max}$ to $(F_0)_{\min}$ variations would again be negligible.

On accepting this, one may conclude that the variation in basic component of solar radio emission with the phase of the solar cycle is only confined to a specific band of wave-lengths—cm and dm regions. Curiously enough, this is also the band in which the slowly varying component is found to exist. It is perhaps worth investigating whether the two might have a common cause. The exact nature of the year-to-year variation and precise evaluation of the band over which the basic component actually varies in

course of a solar cycle will be extremely important. Detailed analysis to this effect is being carried out and will be reported in due course.

We thank Prof. J. N. Bhar and Dr. S. Basu for their advice. Data of solar-radio flux at 2,800 Mc/s belong to the National Research Council, Ottawa, and those at 1,000, 2,000, 3,750 and 9,400 Mc/s to the Research Institute of Atmospherics, Nagoya. We thank Mr. A. E. Covington of Ottawa and Dr. H. Tanaka of Nagoya for sending us their data before publication.

STRUCTURE OF THE RADIO CONTINUUM BACKGROUND AT HIGH GALACTIC LATITUDES

By DR. M. J. S. QUIGLEY and DR. C. G. T. HASLAM

Nuffield Radio Astronomy Laboratories (University of Manchester), Jodrell Bank, Macclesfield, Cheshire

THE purpose of this article is to summarize the results of an investigation into the origin of the continuum radio emission in directions away from the Milky Way, which has been conducted at Jodrell Bank. It now seems possible to reach a general conclusion about the structure of the emission.

The existence of the *North Polar Spur* has been known for some years¹ and, by using data from different observatories, it has been shown² that the *Spur* conforms closely to a small circle for much of its length. A detailed investigation³, which is in course of publication, shows that the complicated structure associated with the *Spur* is almost entirely enclosed within this circle. The diameter of the circle is found to be $113^\circ \pm 3^\circ$ and its centre is at $l_{II} = 330^\circ \pm 2^\circ$, $b_{II} = 19.5^\circ \pm 2^\circ$.

In a series of observations which have been described previously², it was shown that there exists a second high-latitude feature, lying in the southern galactic hemisphere. Because of its situation and appearance we have referred to this as the *Cetus Arc*. The *Cetus Arc* is also found to lie closely along a small circle, although, as with the *Spur*, there is some structure within the *Arc* which falls into no obvious geometrical pattern. With more extensive data than before, we have constructed a stereogram of the *Cetus Arc* in new galactic co-ordinates. This is shown in Fig. 1. The track of the *Arc* was determined from various maps by finding the midpoint of the half-power levels, at various places along the *Arc*. The surveys used were at frequencies of 240 Mc/s (ref. 2), 400 Mc/s (ref. 5) and 178 Mc/s (ref. 6). The points have been plotted as filled circles, open circles and triangles, respectively, and the width to half-power points is indicated by bars. An attempt has been made to fit a circle to the plotted points. Four such circles are shown in Fig. 1. Their parameters are given in Table 1. For most of its length the *Arc* is reasonably well fitted by circle No. 2, but for $b_{II} < 30^\circ$ at $l_{II} \sim 45^\circ$ it diverges from this circle. This may be a real effect or it could arise from either of the following causes:

(1) The *Arc* is being obscured and distorted by the strong emission near the galactic plane.

(2) The position of the ridge is not well defined in this area. For example, on the 400-Mc/s map at latitude -25° , the mean of the longitudes of the 10-unit-contour is at $l_{II} = 40^\circ$, that of the 12-unit contour at $l_{II} = 44^\circ$, and that of the 14-unit contour at $l_{II} = 49^\circ$. This last figure would place the ridge precisely on circle No. 2.

Apart from this anomaly, the *Arc* fits circle No. 2 to within $\pm 2^\circ$ of arc over a total length of 133° . Noting the spread of the values listed in Table 1, we consider that between the points $l_{II} = 40^\circ$, $b_{II} = 35^\circ$ and $(152^\circ, 25^\circ)$ the *Arc* is described by a circle having the following parameters:

Centre (on sphere) at $l_{II} = 100^\circ \pm 3^\circ$, $b_{II} = -33^\circ \pm 3^\circ$.

Diameter, $92^\circ \pm 3^\circ$

In an inspection⁴ of a number of maps of the radio continuum another feature has been identified which seems similar to those described here. We refer to Fig. 2, which is a reproduction of a 240-Mc/s map published by us previously²: full details of the observations are to be found in the reference. The co-ordinate system is the new galactic and the contours are marked in $^\circ K$ above an arbitrary reference-level. Since the beam-width is 1° , and the scans were separated by intervals of 4° in galactic latitude, the map will only represent large-scale features.

Fig. 1. A stereographic projection of the *Cetus Arc* in new galactic co-ordinates. The south galactic pole is at the centre of the stereogram

Table 1

Circle No.	Co-ords of centre on stereogram		Co-ords of centre on sphere		Diameter (deg.)
	l_{II}	b_{II}	l_{II}	b_{II}	
1	97.0	-18.0	97.0	-30.5	95
2	100.0	-22.0	100.0	-33.0	92
3	97.0	-22.0	97.0	-33.0	91
4	98.0	-19.0	98.0	-32.0	97

Apart from the steep rise in intensity at low latitudes, the obvious structural features in the region are the projections from the borders of the map at latitude $b_{II} \sim 40^\circ$, which are joined by a band of emission at least 6° K brighter than its surroundings. For the right-hand projection there is some indication that it issues from the galactic plane, but the area of the survey is insufficient to include all the feature.

The 240-Mc/s map may be compared with more extensive surveys, such as those of Seeger *et al.*⁵ at 400 Mc/s, and of Turtle and Baldwin⁶ at 178 Mc/s, which confirm the existence of the large-scale structure apparent in Fig. 2. They also indicate that the projecting spurs at latitude 40° can be traced back to the galactic plane at longitudes $l_{II} \sim 87^\circ$ and $\sim 157^\circ$. We are therefore observing a structure similar to the *Cetus Arc* and the *North Polar Spur*, that is, a belt which projects from the galactic plane, and returns at a different longitude. The resemblance is strengthened by the fact that the belt becomes weakest at its furthest point from the galactic plane. However, it is distinguishable above the background at all points. Its minimum temperature (measured above adjacent areas of sky) at 240 Mc/s is about 6° K and the maximum 25° K. We propose to consider this belt as a coherent feature, and we shall refer to it as *Loop III*, the numeral indicating that this is the third high-latitude feature to be identified. It is also the least bright of the three. Its existence has been noted independently in a recent paper by Seeger *et al.*⁷

As with the *Spur* and the *Cetus Arc*, the geometry of *Loop III* has been investigated by plotting it on a galactic stereogram, which is reproduced in Fig. 3. The position of the *Loop* was measured from the same surveys, and in the same manner, as was that of the *Arc*. The figure shows three circles which have been fitted to the *Loop*. Their parameters are listed in Table 2.

Table 2

Circle No.	Co-ords. of centre on stereogram		Co-ords. of centre on sphere		Diameter (deg.)
	l_{II}	b_{II}	l_{II}	b_{II}	
1	124	2	124	11.5	71
2	124	6	124	14.5	71
3	123	3.5	123	13.0	72

For most of the *Loop*, circle No. 1 gives the best fit, but the bulge at $l_{II} = 155^\circ$ to 160° , $b_{II} \sim 30^\circ$, is more closely fitted by circle No. 2. The deviations of the *Loop* from circle No. 1 are at most $\pm 3^\circ$ of arc, so we adopt this as the best fit to the plotted points and assert that the *Loop* is reasonably well described by a circle which has the following parameters:

Centre (on the celestial sphere) at $l_{II} = 124^\circ \pm 1^\circ$,
 $b_{II} = 11.5^\circ \pm 2^\circ$.

Diameter, $71^\circ \pm 2^\circ$.

Fig. 2. 240-Mc/s isophotes of a region in the north galactic hemisphere. The brightness temperatures are marked in deg. K above an arbitrary level

Fig. 3. A stereographic projection of *Loop III* in new galactic co-ordinates. The north galactic pole is at the centre of the stereogram

Fig. 4. A stereographic projection of the celestial sphere, in new galactic co-ordinates. Objects which lie wholly or predominantly in the northern galactic hemisphere have been projected from the south galactic pole and vice versa. The *North Polar Spur*, the *Cetus Arc*, and *Loop III* are outlined by filled circles, open circles, and crosses, respectively. Various preferred directions have been inscribed, as follows: the supergalactic pole (ref. 9) and equator (NGH only); the *Centaurus A* extended radio source (ref. 9); the Large and Small Magellanic Clouds (SGH). The least bright area in the northern galactic hemisphere is shown as a shaded patch in the upper right-hand corner

The errors in the foregoing values are estimated from the spread of values in Table 2 and from the deviations of the *Loop* from the circles.

It is interesting to represent the *Spur*, the *Cetus Arc*, and *Loop III* together in the same stereogram to see if they bear any relation to each other or to the galactic plane, points of minimum halo emission, etc. It is difficult to draw all three of the features on a straightforward stereogram because of the rapid expansion of the scale outside the primitive. However, we may adopt the device of projecting objects which lie wholly or predominantly in the northern galactic hemisphere from the south galactic pole, and those in the southern hemisphere from the north pole. This procedure has been followed in constructing Fig. 4. The *Spur*, the *Cetus Arc*, and *Loop III* are outlined by filled circles, open circles, and crosses, respectively. Marked also are a number of directions to which some interest is attached. These are detailed in the caption.

We have inspected the figure and have been unable to find any special geometrical relationship among the dispositions of the three arcs, or between them and any of the various preferred directions. However, using our results, Meaburn⁶ has demonstrated a remarkable positional coincidence between *Loop III* and a number of high-velocity neutral hydrogen clouds. The three arcs do seem to have one feature in common: their brightest parts lie near to the galactic plane, and the brightness diminishes with increasing latitude. This fact may be significant for their interpretation.

The three arcs and their associated features appear to account for a very large proportion of the structure observed in the radio continuum away from the galactic plane, and perhaps also for a substantial part of the total

halo emission. It is hoped in the future to carry out more detailed mapping of the *Cetus Arc* and *Loop III*, which so far have not been examined at high resolution.

AGE OF THE WEARDALE GRANITE

By F. J. FITCH

Department of Geology, Birkbeck College, University of London

AND

Dr. J. A. MILLER

Department of Geodesy and Geophysics, University of Cambridge

THE Weardale granite was encountered at 1,281 ft. depth beneath unconformable Carboniferous Limestone in the Durham Colleges Geology Department Rookhope borehole (NY 35/937,428), West Durham, in 1960. The possibility that a high-level granite might exist beneath the Alston block was first suggested by Dunham in 1934, when he described the concentric pattern of the zonal mineralization in the area¹. A regional gravity survey by Bott and Masson-Smith gave support to this suggestion and indicated the probable presence of a granite with cupolas close beneath the mineralized area². As the mineral veins of West Durham are found in Carboniferous strata and bear a distinct petrographical resemblance to those of Devon and Cornwall, it was thought at that time that the postulated granite might be Variscan in age.

The first results of the research borehole put down by Dunham *et al.* to test these hypotheses appeared in 1961, when they reported that, although granite had been found, it was seen to be unconformably overlain by Lower Carboniferous strata, and must therefore be pre-Carboniferous in age³. At the same time isotopic age investigations of two samples of this newly discovered granite were reported by Dodson and Moorbath⁴. Their conclusions from these investigations were: (1) that the Weardale granite was emplaced in Middle or Late Devonian times around 362 ± 6 m.y.; (2) that it is significantly younger than the Shap granite, but possibly contemporaneous with the Skiddaw granite. We find it difficult to accept the conclusions of Dodson and Moorbath and have made a further

isotopic age investigation of the granite as part of an extended programme of geochronology of the rocks of north-east England.

A full description and discussion of the geological results of the Rookhope borehole has recently been presented to the Geological Society of London by Dunham *et al.*⁵. Both in the discussion of this paper and in the discussion of an earlier paper by Brown, Miller and Soper on the intrusions of the English Lake District⁶, the same unresolved difference of opinion can be found. One school of thought (K. C. Dunham, Miller, Brown, Bowie) believed that the Late Devonian age obtained for the Weardale Granite by Dodson and Moorbath should be treated with some caution: (a) because of the probable effects of later mineralization; (b) because abnormal variations in the radioactivity of the granite and in the Rb/Sr ratios have been noted, suggesting inhomogeneity, and the possibility that not all the rock crystallized at the same time. In the other view (A. C. Dunham, Soper) a late Devonian age was accepted because it was thought possible that late potassic differentiates of the British Caledonian 'Newer Granite' magma could have been emplaced in Middle, or even Upper, Devonian times.

Four new potassium-argon age determinations are reported in Table 1. Specimen FM 271 is a muscovite-alkali-granite-gneiss which has suffered several phases of metasomatic alteration and intermittent cataclasis. Specimen FM 272 is a chlorite (biotite)-muscovite-alkali-granite-gneiss less affected by subsequent metasomatism. Specimen R/14 is a muscovite concentrate supplied by

the Oxford Isotope Laboratory, and is similar material to that on which the original age work was done by Dodson and Moorbath⁴.

The analytical methods used at Cambridge were similar to those described by Miller and Brown⁷.

Table 2 summarizes the relevant age data at present available. Geologically, the Weardale granite can be said to be pre-Viséan. The rocks into which it is intruded are not seen in the borehole, but by analogy with the nearby Cross Fell Inlier the youngest rocks which are involved as host-rocks would most probably be late Silurian in age⁸.

Table 2. SUMMARY OF RELEVANT AGE DATA ON WEARDALE GRANITE

Sample	Method	Age and error (m. y.)	Ref.
1396'	Rb/Sr muscovite	360 ± 12	Dodson and Moorbath, 1961

Beneath the Carboniferous unconformity, granite was continuously exposed in the Rookhope borehole from 1,281 ft. to 2,650 ft. Dunham *et al.*⁶ described it as having a low-dipping foliation in the upper part, becoming less obvious below 2,225 ft. depth. Mineralogically it is said to contain biotite, abundant muscovite, low albite, orthoclase, microcline and quartz. Many mineral veins cut the granite: pyrrhotine is present in these veins below 1,355 ft., and the source of mineralization is presumed to lie beneath the granite, which has acted as a channel for the rising fluids.

The specimens of Weardale granite which have been used so far in age investigations all come from the foliated upper portion of the granite. Further analysis of specimens from the lower part of the borehole should be undertaken in the future.

The geological history of the foliated portion of the granite is complex, but can be largely understood by careful study of thin sections: and appears to be as follows:

(A) *Initial crystallization* of muscovite-biotite alkali-granite.

(B) *Foliation and partial high-temperature metasomatism*: during this first subsequent event shearing and cataclasis converted the granite above 2,225 ft. to a granite-gneiss. Original quartz grains were completely granulated and reduced to (now recrystalline) lensoid masses: primary biotite and muscovite were streaked out along shear planes. Accompanying this strong mechanical metamorphism, but more restricted in its distribution, was a wave of metasomatic recrystallization. In the rocks most strongly affected by this metasomatism, original feldspar is strongly attacked along its margins by the growth of myrmekite fringes, large new muscovites grow in random orientation, overprinting earlier textures and mineral fabric, new medium- and fine-grained quartz and albite appear, and there is partial and, in places, complete, recrystallization of early quartz, micas and feldspar. This first subsequent event was probably the result of renewed intrusive activity at depth, only partially reactivating the consolidated upper facies of the granite pluton.

(C) *Low-temperature metasomatism*: one or more episodes of low-temperature metasomatism associated with 'Variscan' mineralization can also be distinguished. During these events the granite suffered mild brecciation in places, and any primary biotite that was still present was largely converted to chlorite and iron ore. Sericitization and the appearance of other secondary minerals, such as calcite, was widespread, especially close to mineral veins.

It was suggested by Dodson and Moorbath⁴ that the coincidence of apparent isotopic ages obtained by both the K/Ar and Rb/Sr methods makes it probable that the weighted mean of their results (362 ± 6 m.y.) was close to the true age of the emplacement of the Weardale granite.

This is an invalid argument when applied to a mineral separation from rock material with a complex metasomatic history. Analysis of the same contaminated mineral sample by different methods may well produce similar apparent ages within the experimental errors, and the fact that almost identical results were obtained in this case does not necessarily imply that they reflect the age of original crystallization.

Examining first the K/Ar results from muscovite, it can be seen that each muscovite sample extracted from the granite will be a mixture of muscovites of different ages. They will each contain varying proportions of some or all of the following: (1) original primary muscovites; (2) original primary muscovites giving low ages because of subsequent cataclasis or partial recrystallization; (3) large secondary muscovites of the early high-temperature metasomatism; (4) sericite of later low-temperature metasomatism(s); (5) secondary muscovites or sericite giving low ages because of mild cataclasis and other effects associated with the subsequent low-temperature metasomatism(s).

Analysis of these samples will produce average age results none of which will be the true age of any of the events that affected the granite. As the largest muscovite fractions present in the rock, however, are those occurring under (2) and (4) above, the average results should normally fall somewhere between the ages of (2) and (4). Thus the highest K/Ar result (392 ± 6 m.y.) can be accepted as a good minimum age for the gneissification of the granite and the lowest result (356 ± 12 m.y.) can be taken as being greater than the age of subsequent low-temperature metasomatism(s). The Rb/Sr results must be interpreted similarly. Each muscovite sample used is a mixture of muscovites which crystallized in a different isotopic environment. None of the subsequent metasomatisms which have affected the Weardale granite would have produced isochemical recrystallization. When secondary muscovite crystallized in the rock, its initial strontium-isotope ratio would have been related to the new metasomatic environment and not to the average strontium-isotope composition of the rock (as is assumed under conditions of isochemical metamorphism). Thus the Rb/Sr results (365 ± 12 m.y. and 360 ± 12 m.y.) indicate, as do the K/Ar results, an average age somewhere between the age of gneissification and that of the 'Variscan' mineralizations. Taking into consideration the considerable variability in the proportions of true primary (1) and secondary muscovite (3) in the samples, one possible inference from the low total spread of both K/Ar and Rb/Sr results from muscovite (392 ± 6 m.y.- 356 ± 12 m.y.) would be that the age of primary crystallization cannot be very much before that of gneissification. A Pre-Cambrian age of initial crystallization would not appear to be likely for this granite. The results definitely suggest initial intrusion during the main late Silurian/Lower Old Red Sandstone Caledonian orogenic/magmatic event (say within the period 425-400 m.y.) followed by re-activation and gneissification of this early facies by further intrusive activity before 392 ± 6 m.y. This interpretation is consistent with other work on the 'Newer Granite' suite published recently^{9,10}.

The ages of the subsequent low-temperature metasomatisms, associated with 'Variscan' mineralization, can only be indicated as less than 356 ± 12 m.y. from the muscovite results alone, but further evidence is obtained from the one 'chlorite' result. This 'chlorite' sample contains a small amount of sericite and muscovite impurity, but is largely composed of chlorite, which crystallized during the widespread mineralizing episode. As the muscovite impurity will raise the apparent age, the age of 255 ± 12 m.y. obtained from this fraction is a maximum age for the last major mineralizing event in this area. Two widespread early episodes of the so-called 'Variscan' mineralization are known throughout England about 290 m.y. and 225 m.y., and metasomatism associa-

ted with these episodes can be shown to cause partial recrystallization and markedly to influence the K/Ar ages of earlier igneous rocks¹¹. It is thought most probable that the Weardale granite acted as a channel for the upward migration of metasomatizing fluids during both these episodes and possibly also during later much less intense mineralizing events.

We thank Prof. K. C. Dunham and Sir Edward Bullard for their advice and for providing samples of granite from the Rookhope borehole; also Miss D. E. Bate for the careful work involved in separating the small amount of 'chlorite' from sample FM 272.

RECENT FINDS IN THE UPPER CARBONIFEROUS OF SOUTH-WEST ENGLAND AND THEIR SIGNIFICANCE

RECENT field work by myself and colleagues, and two new faunal discoveries, have led to a re-appraisal of the stratigraphy and structure of the Upper Carboniferous of south-west England. The evidence suggests that, instead of two simple successions younging towards the axis of a synclorium, there may be a series of blocks each with its individual stratigraphical succession and separated from each other by major thrust faults.

Our present knowledge of the stratigraphy stems from the work of Owen^{1,2} in the south, and Prentice³⁻⁵ in the north, who both suggested that the structure was broadly that of a synclorium with the succession younging southwards in the north and northwards in the south.

In the southern portion of the synclorium the accepted succession of formations has been²: Crackington Measures → Bude Sandstones → Welcombe Beds.

Goniates^{2,6} prove a Namurian (E_2 to R_{2b}) for the Crackington Measures and a Lower Westphalian age (G_2) for the Welcombe Beds^{7,8}. However, the contacts of the Bude Sandstones with the neighbouring formations are faulted and there is no unequivocal field evidence that they lie between the Crackington Measures and the Welcombe Beds. In fact, Ashwin⁹ suggested on structural grounds that the Welcombe Beds formed the core of an anticlinorium and underlay the Bude Sandstones.

The Bude Sandstones have been given a Lower Westphalian age because of plants identified by Crookall¹⁰ as belonging to the Lower Coal Measures; but no molluscs had been found until in 1963 I discovered goniates and lamellibranchs on the coast at Sandy Mouth (SS 202100) in a black sulphurous shale 10 yd. north of the steps leading down to the beach. Specimens were sent to Dr. W. H. C. Ramsbottom, who made further collections on the foreshore and identified the goniates as *Weidyceras* sp. nov. and the lamellibranchs as *Dunbarella* and *Caneyella*. Dr. Ramsbottom considers that a horizon in the Lower Westphalian "just above the *G. listeri* Marine Band" is indicated.

Thus the precise age of part of the Bude Sandstones is established. Field work by myself and Mr. J. P. B. Lovell¹¹ suggests that the goniatic horizon is about 1,000 ft. above the base of the Bude Sandstones, which are about 4,000 ft. thick altogether. The Bude Sandstones are therefore undoubtedly younger than the Crackington Measures, but unfortunately their relationship to the Welcombe Beds is still uncer-

tain, as it is not clear where in the Lower Westphalian the Welcombe Beds should be placed.

In the northern part of the synclorium recent work began with the important pioneer work of Prentice³⁻⁵, who suggested that the stratigraphical succession passed from turbidites of the Instow Beds into a 'coal measure' facies, the Northam and Abbotsham Beds, and continued through 'slumped' Greencliff Beds into more turbidites, the Cockington Beds. The central part of Prentice's succession has been modified by De Raaf, Reading and Walter¹² and Walker¹³, and now stands as follows:

Bideford Group	Cockington Beds 700 ft.	'Identifiable gastrioceratids'	'Turbidite'
	Greencliff Beds 500 ft.	<i>C. communis</i> at base	'Slump'
	Abbotsham Formation 1,200 ft.	<i>A. lensulcata</i> near top	6 paralic cycles
	Northam Formation 1,450 ft.	<i>C. (?) bellula</i> near the base	3 paralic cycles
	Westward Ho! Formation 1,660 ft. +	No fossils	Laminated silty mudstones with turbidites
	Instow Beds 1,500 ft.	<i>G. listeri</i> near top	'Turbidite'
	Limekiln Beds 100 ft.	R_1 , R_{2a} goniatices	Siliceous siltstones and black shales

Fig. 1. Sketch map of localities and Upper Carboniferous formations in the coastal regions of north Devon and Cornwall

Recently, Dr. D. Boschma and Dr. R. G. Walker found lamellibranchs in loose slabs of sandstone, undoubtedly fallen from a horizon 80 ft. above the base of the Abbotsham Formation in the top of the first paralic cycle. The locality is on the coast west of Bideford (SS 411278). Dr. R. M. C. Eagar and Mr. M. A. Calver have examined the lamellibranch fauna. They state that variants grade from *Carbonicola* (?) *bellula* (Bolton) to short *Carbonicola* (?) virtually identical with forms shown in Eagar's Pl. xii, Fig. 3 "northern series"¹⁴. Both the pattern of growth of the shells and also the final form reached are particularly characteristic of a horizon below the *Gastrioceras subcrenatum* Marine Band and above that of *G. cumbriense*. Probably the horizon is only a short distance below the *G. subcrenatum* Marine Band.

If, therefore, the lower part of the Abbotsham Formation is Namurian it is important to look at the evidence for the foregoing succession, which places the Instow Beds with a *G. listeri* (Lower Westphalian) fauna 3,000 ft. below the Abbotsham Formation, the lower part of which is Namurian.

Let us first take the palaeontology. There is no doubt of the existence of a *G. listeri* fauna at the top of the Instow Beds as described by Prentice³. Simpson¹⁵ determined non-marine lamellibranchs found by Rogers at Abbotsham Cliff in the upper part of the Abbotsham Formation (at the top of cycle 4)¹² as belonging to the *lenisulcata* zone and those found in Roberts quarry (SS 470264), which Prentice⁴ considered lay just above the Abbotsham Formation, as belonging to the *ovalis* (= *communis*) zone. Eagar and Calver (personal communication) have confirmed that a high *lenisulcata* or low *communis* zone is likely for these faunas.

The only goniatites at present known from the Abbotsham Formation are 'minute goniatites' mentioned by Prentice⁴, which occur in shale near the base of Cycle 2 (ref. 12) immediately above the *C. (?) bellula* lamellibranchs. These goniatites could represent the *G. subcrenatum* Marine Band, one of the most widespread marine horizons in Europe. Support to this is given by correlating paralic cycles of the Bideford Group ranging from basinal mudstones to coastal plain sediments^{12,13} with the cycles (defined by marine bands) of the Namurian and *lenisulcata* zone of the South Crop of the South Wales coalfield^{16,17}. There, four major cycles occur in the Namurian and five to six occur in the *lenisulcata* zone¹⁷. In the Bideford Group there are nine, and *C. (?) bellula* occurs at the top of the fourth.

If we now turn to the field evidence, the coastal section and field mapping by myself and my colleagues between Bideford and the coast firmly establish the succession Westward Ho! → Northam → Abbotsham Formation^{12,13}. There is complete exposure on the coast, and though faults and folds exist, correlations of individual layers can be made across them. The succession generally youngs southwards and one might expect to find the Instow Beds at the northern end of the section. Recent sands of Bideford Bay, however, obscure the solid outcrop and the lowest exposed stratum is still in the Westward Ho! Formation. The evidence for a transition

between the Instow Beds and the Westward Ho! Formation is on field mapping and the recognition of lithologies in a single quarry. In this area facies differentiation inland is extremely difficult and mapping is inconclusive. Prentice⁴, however, considered that the base of his Northam Beds was to be seen at Hubbastone Quarry (SS 463297), where it lay abruptly on the Instow Beds. Although, as Walker¹³ pointed out, the upper part of Hubbastone Quarry is composed of grey silty mudstones similar to much of the Westward Ho! Formation rather than a 'coal measure' type of sedimentation as Prentice thought, there is no real disagreement here, since the Westward Ho! Formation equals the lower half of Prentice's Northam Beds. The question is whether the greywackes in the lower part of the quarry are the Instow Beds. While admitting that they look very similar to much of the Instow Beds, I consider that they may equally well be turbidites within the Westward Ho! Formation and that therefore the evidence for a formational junction in this quarry is not conclusive.

In the upper part of the succession, Prentice considered that the succession went from the 'coal measures' Abbotsham Beds through 'slump' Greencliff Beds, indicating steepening slope into the turbidites of the Cockington Beds. The upper part of the Greencliff Beds is infolded with the Cockington Beds and there is no reason to suspect this junction. The lower part, however, is faulted against the Abbotsham Formation. Structural disturbance in the Greencliff Beds is very considerable and exposure is by no means complete. Unlike the Westward Ho! to Abbotsham Formation part of the section, there is no clear field evidence that the Abbotsham Formation passes sequentially into the Greencliff Beds. An alternative explanation is that at the Abbotsham Formation to Greencliff junction there is a major tectonic dislocation.

The palaeontological position of the Cockington Beds is uncertain. Prentice⁴ claimed that it contained "identifiable gastrioceratids younger than the *lenisulcata* zone". On the other hand, Prentice and Thomas⁸ state that it contains *G. subcrenatum*. Lithologically, the Cockington Beds are indistinguishable from the Bude Sandstones and, like the latter, they occur adjacent to the Welcombe Beds. It is more likely, therefore, that the Cockington Beds also belong to the *lenisulcata* zone.

Thus an analysis of the present results, admittedly inconclusive, suggests that the stratigraphy may be more complex than the established succession allows. An alternative hypothesis which appears to fit the facts better is that there are at least four distinct successions in the Upper Carboniferous of south-west England which are partly time equivalents of each other.

Many problems remain. The position of the Welcombe Beds is still uncertain and will remain so until there is closer palaeontological control, and until field mapping by Mr. L. Moore, of King's College, London, around Hartland Point is complete. They may prove to be younger than the adjacent formations or to be their time equivalents, but they are unlikely to be older. The position of *communis* zone lamellibranchs recorded by Simpson¹⁵ was

Table 1. UPPER CARBONIFEROUS STRATIGRAPHY OF COASTAL REGIONS OF NORTH DEVON AND CORNWALL

	Westphalian <i>lenisulcata</i> - <i>communis</i>	Welcombe Beds <i>G.</i> (c. 2,000')				Bideford Group	Instow Beds <i>G. listeri</i> (1,500')
		<i>G.</i> <i>listeri</i>	Bude Sandstones <i>G. listeri</i> (4,000')	Cockington Beds <i>G. subcrenatum</i> (700')	Abbotsham Formation <i>lenisulcata</i> near top <i>C. (?) bellula</i> near base		
		<i>G. subcrenatum</i>			(1,200')		
Namurian	<i>G.</i> ₁				Northam Formation no fossils (1,450')		Lamekin Beds <i>R.</i> ₁ , <i>R.</i> _{2a} (100')
	<i>R.</i> ₁		Crackington Measures <i>E.</i> ₁ - <i>R.</i> _{1a} (c. 3,000')	Greencliff Beds no fossils (500')	Westward Ho! Formation no fossils (1,660' +)		
	<i>H.</i> ₁						
	<i>E.</i> ₁						

thought by Prentice⁴ to be above the Cornborough Sandstone which forms the top of the Abbotsham Formation. The location is inland, east of Bideford, and the formation may there continue up into the *communis* zone.

There is, on the foregoing hypothesis, a series of laterally equivalent successions, none of which contains a great thickness of Upper Carboniferous strata. What remains of the fill of the Culm geosyncline neither extends very far into the Lower Westphalian nor is large in volume.

To bring together such sedimentologically distinct formations lateral translations of considerable magnitude are required. Dearman¹⁸ has emphasized the importance of north-north-westerly dextral wrench faults in Cornwall and south Devon. Although wrench faults undoubtedly complicate the picture, their displacement is seldom more than a mile and is insufficient to give the required movement. It is suggested, therefore, that there are major thrust faults, not easily detectable in the very low topography, which separate a number of structural units. These faults are most probably very low angle thrust zones of broken and contorted strata along which individual blocks have ridden, rucking up the strata within each block to give the tight fold pattern so characteristic of the Carboniferous in south-west England. It is even possible that some blocks originally deposited to the south have overridden the more northerly ones, so that to-day the original sedimentological pattern is reversed, as in the Alps. There seems to be no other explanation, if the suggested stratigraphy proves correct, for the turbidites of the Limekiln Beds and Instow Beds lying to the north of the northerly derived Westward Ho! Formation and paralic Bideford Group.

THE positive identification as *Gastrioceras subrenatum* (by W. H. C. Ramsbottom) of the goniatites from Rowden Cliff (SS 391252), in beds formerly attributed by me to the Cockington Beds (ref. 4, 402), shows that these are really the equivalent of the Instow Beds. This marine band, and one with *G. listeri*, also recurs repeatedly in the cliffs between Clovelly and Hartland (Moore, L. R., personal communication). Dr. H. G. Reading's hypothesis, which he has kindly allowed me to study, is, however, only one of several possible alternatives. His equation of Greencliff Beds here, with the Limekiln Beds of the Fremington region, contradicts my assertion that the former follow in stratigraphic order above the Abbotsham Beds. The evidence for this had to be omitted from the *Geological Society Journal* and it is worth while stating it now in detail. The coast section at Greencliff (Fig. 1) is not as clear as could be wished, but my interpretation is as follows. The coarse white sandstone (Cornborough Sandstone; Fig. 1, a) is followed by a few feet of black shales with *Planolites*, and then by the 'culm' bed (b), here strongly shattered and quartz-veined. This, in turn, is followed by laminated black silty shale with ironstone nodules (c). The section is then faulted; south of the second fault are 'turbidite' grits (d) which young to the north, and which rest on the laminated slumped siltstones (e) of the Greencliff Beds. These continue, still younging northwards, to south of the Limekiln, where they rest on black cleaved mudstone with ironstone nodules (f). It seemed reasonable to equate these with the lithologically similar beds (c) above the Cornborough Sandstone, and thus to recognize no major structural translocation at this point. Although there is undoubtedly faulting in this section (at d) the faults are high angle, and can be traced across the foreshore as north-westerly and north-easterly faults with a wrench component. Half a kilometre to the south, however, undoubted low-angle thrust faults appear (ref. 4, 400), and it is south of these that the beds contain *G. subrenatum*. It seems likely that it is these faults which are the most significant, bringing up the Instow Beds in tectonic superimposition with the lithologically similar Cockington Beds.

Similar relationships are seen inland. On the left bank of the River Torridge above Bideford, for example, black cleaved mudstone appears to overlie the Cornborough Sandstone, and to occupy the whole river bank from Bideford Bridge to Ford Rock (SS 453258); here they are overlain by grey siltstones (Greencliff Beds?) which are now well exposed in the new road cutting. South of these a group of greywacke sandstones is much shattered, and *Gastrioceras* occurs north and south of the confluence of the stream (SS 453252). The outcrop of the 'culm' and the underlying Cornborough Sandstone has been mapped eastwards from the Torridge to Gammaton (SS 490262), and regularly has a broad outcrop of laminated siltstones to the south, which is in turn followed by the outcrop of

Fig. 1 Arrows indicate observed younging

greywacke sandstones. Old mining records show that the 'culm' outcrop continues eastwards to beyond the River Taw, and further east still E. E. Swarbrick has found a group of greywacke sandstones, the Alswear Formation apparently overlying the paralic Mole Valley Formation (= Northam and Abbotsham Beds) south of South Molton.

The interpretation of relationships between the base of the Westward Ho! Formation and the Instow Beds depends on the investigation of Hubbastone Quarry, Appledore. Since the Westward Ho! Formation can be mapped widely over the area north-east of Northam, and it is admitted that the beds at this quarry are lithologically similar to them, there seems no reason why they should not be regarded as part of this Formation. The lower horizons in this quarry, however, have abundant turbidite structures, and the shales are strongly pyritic—features which characterize the Instow Beds. It should be noted that Inkerman Rogers (1910) recorded 'marine nodules' from this quarry, though no specimens are extant.

The argument that it is implausible that the *lenisulcata* zone should be more than 4,000 ft. thick I find difficult

to accept; it is even more difficult to believe in facies changes from the 100 ft. of the Limekiln Beds southwards into 3,000 ft. of paralic sediments, and in giant tectonic translocations bringing these facies into juxtaposition. It is, moreover, difficult to see, without supposing major tectonic translocation, how deltaic sediments believed to have come from the north could have accumulated south of the zone of thin 'distal turbidites' represented by the Limekiln Beds: or how the paralic Abbotsham Beds could lie south of turbidites derived from the south, and north of turbidites derived from the north. Dr. Reading's theories then introduce more problems than they solve.

This is not to say that Dr. Reading's interpretation is impossible, nor can either of our successions be fully proved. The answer lies in the accumulation of more data, and it is hoped that our controversy may stimulate its collection.

APPLICATION OF AN AGAR-AGAR DIFFUSION PROCEDURE TO PESTICIDE RESIDUE ANALYSIS AND TO THE CHOLINESTERASE SCREENING OF CANDIDATE PESTICIDES

By DR. K. I. BEYNON and G. STOYDIN

'Shell' Research, Ltd., Woodstock Agricultural Research Centre, Sittingbourne, Kent

SANDI *et al.*¹⁻³ have described an agar-agar diffusion procedure which can be used for the analysis of crops, soils, and animal tissues for residues of organophosphorus and carbamate insecticides. In their procedure, a layer of agar-agar 5 mm thick containing cholinesterase was prepared from human crassamentum and bromothymol blue, at pH 7.8-7.9. An isopropanol solution (0.1 ml.) of the insecticide was applied to a hole in the agar-agar. Diffusion was allowed to take place for 18 h at room temperature. The plate was then sprayed with acetylcholine chloride solution and the blue layer turned yellow within 30 min, apart from those areas where the enzyme had been inhibited, which remained as blue circles.

A rectilinear relationship was found to exist between log (amount insecticide) and the diameter of the ring. When the same amount of different compounds was applied to the plate, the strongest inhibitor produced the largest blue circle.

Sandi *et al.*^{2,3} reported that 0.003 µg of parathion could be detected in standard solutions after oxidation and described³ the application of the method to the determination of residues of parathion in edible oils down to a level of 0.75 p.p.m.

The procedure is of interest since it will detect very small amounts of some insecticides using the simplest of apparatus. However, the precision of the method as described by Sandi *et al.* does not appear to be good since the increase in diameter of the rings with increasing amounts of compound is not very great.

We have varied the experimental conditions using human plasma in an attempt to improve the precision of the method for residue analysis. We have also investigated the use of fly-head cholinesterase particularly as a method for the screening of the cholinesterase inhibition produced by candidate insecticides.

The experimental procedures differed from those described by Sandi² only in the following points. In some experiments human plasma was used at concentrations of

1-8 per cent (vol./vol.) relative to the agar-agar gel. In other experiments cholinesterase from fly-heads was used and the pH of the gel was adjusted to 7.5, instead of 7.8-7.9 as recommended by Sandi for plasma. The lower pH gave more consistent results. The supernatant solution from the maceration of fly-heads with 0.9 per cent saline (1 ml.-0.08 g of fly-heads) was used at a concentration of 5 ml. for every 60 ml. of agar-agar gel. In the preparation of gel mixtures containing fly-head cholinesterase the gel temperature was not allowed to exceed 40° C after the fly-head concentrate had been added.

The sizes of the inhibition rings produced by different concentrations of organophosphorus compounds are summarized in Figs. 1-3. It is evident that very small quantities of organophosphorus compounds produce measurable inhibition rings and 0.001 µg of 'Birlane' (1-chloro-2-(2,4-dichlorophenyl)-vinyl diethyl phosphate) and dichlorvos and 0.01 µg of mevinphos can be detected using fly-head cholinesterase. The precision of the procedure was not good, in that an increase of only 5 mm in ring diameter corresponded to a 2-5-fold increase in the amount of compound. Variation of the gel thickness and plasma concentration did not affect the precision of the procedure (Fig. 2).

Mevinphos was added to isopropanol extracts of lettuce, carrots, onions, potatoes, sugar beet and tomatoes to correspond to 0.05 p.p.m. in the original sample. The extracts were neutralized, if necessary, by the addition of N/10 NaOH. Aliquots of the extracts (50 ml. = 25 g crop) were concentrated to 5 ml. by blowing a jet of clean air over the surface of the solution. The mevinphos content of each solution was measured by the agar-agar diffusion procedure at a plasma concentration of 3 per cent v and gel thickness of 5 mm. Standard solutions of mevinphos and crop extracts containing no mevinphos were run on the same plate as the treated extracts. The neutralized, untreated extracts produced no inhibition rings. The treated samples produced inhibition rings of 26-28 mm and corresponded to recoveries of 115 per cent

from carrots, lettuce, potatoes and sugar beet, and 130 per cent from onions and tomatoes. While the recoveries were high the ring diameter corresponding to 100 per cent recovery was 25 mm, which was close to the values observed with the treated samples. The 1-3 mm difference, however, corresponds to a 15-30 per cent difference between the actual and theoretical recovery and this arises from the poor precision of the method.

While the agar-agar diffusion procedure is not precise for most residue analysis it is useful for the approximate determination of residues of organophosphorus and carbamate insecticides when sophisticated equipment is not available.

Fig. 1. Inhibition rings produced by mevinphos and dichlorvos using 4.5 mm layers of gel and 3 per cent concentration of human plasma. ■, Mevinphos, dimethyl 1-methoxycarbonyl-1-propen-2-yl phosphate; ●, dichlorvos, 2,2-dichlorovinyl dimethyl phosphate

Inhibition rings produced by 'Birlane' 1-chloro-2-(2,4-dichlorophenyl) vinyl dimethyl phosphate. ●, 4.5 mm gel layer 1 per cent plasma concentration; □, 4.5 mm gel layer 3 per cent plasma concentration; ○, 4.5 mm gel layer 5 per cent plasma concentration; ■, 2.0 mm gel layer 3 per cent plasma concentration

Fig. 3. Inhibition rings produced by organophosphorus compounds after agar-agar diffusion (5 mm layer) using fly-head cholinesterase. ●, Dichlorvos; ○, 'Birlane'; ■, mevinphos

In spite of the poor precision the method is useful for the routine screening of candidate insecticides for their *in vitro* inhibition of insect enzymes. While many precise procedures are available⁴ for measuring the inhibition of cholinesterase by organophosphorus compounds

Table 1. APPLICATION OF AGAR-AGAR DIFFUSION TO CHOLINESTERASE SCREENING

Structure of insecticide	Diameter of inhibition ring (mm) produced by 1.5×10^{-4} moles of the insecticide	pI_{50} *
$(C_2H_5O)_2P(O)OC(=CHCl)-C_6H_3Cl_2-CH_3$ ('Birlane')	49	8.7
$(CH_3O)_2P(O)OC(=CHCl)-C_6H_3Cl_3$	46	7.9
$CH_3NHC(O)O-C_6H_3(CH_3)_2$	38	7.0

$(CH_3O)_2P(S)O-C_6H_3S-N=N$	<1	5.9
$(C_2H_5O)_2P(S)O-C_6H_3S-N=N$	<1	<1

* - \log_{10} (molar concentration of compound to produce 50 per cent inhibition of fly-head cholinesterase).

and carbamates, such methods are time-consuming when many dozens of compounds are to be examined each week.

Several candidate insecticides (1.5×10^{-8} moles in 0.1 ml. IPA) were applied to an agar-agar plate (5 mm thickness containing fly-head cholinesterase) and the layer was sprayed with acetylcholine chloride after 18 h. The inhibition rings were then measured. In addition the pl_{50} values for each compound were measured by a precise procedure by plotting the percentage inhibition of fly-head cholinesterase produced by different concentrations of each compound. The enzyme activity for such measurements was determined by the method described by Michel⁵, and the organophosphorus compounds and enzyme were incubated at 25° C for 30 min before the determination of the activity.

The ring diameters are compared with the pl_{50} values in Table 1 and the results suggest that the agar-agar diffusion method can provide an indication of the inhibitory powers of the compounds examined. The inhibition of up to 36 compounds can be determined at the same time on one 33 cm \times 33 cm agar plate.

While screening by the diffusion method gives far less precise information than pl_{50} values, the procedure permits the rapid examination of a large number of compounds and is useful in preliminary work.

EVALUATION OF ION EXCHANGE CARTRIDGES FOR FIELD SAMPLING OF IODINE-131 IN MILK

By R. H. JOHNSON, jun., and T. C. REAVEY

Northeastern Radiological Health Laboratory*, Winchester, Massachusetts

IODINE-131 may be introduced into the environment through the normal discharges from nuclear reactors and nuclear fuel processing plants, through industrial accidents and through the detonation of nuclear weapons or other nuclear devices. The volatility of iodine and many of its compounds makes it one of the radio-elements most likely to escape to the environment in accidents at nuclear reactor plants. In unseparated fission products, this radionuclide is the critical element in terms of radiation dose to the population for early periods from radionuclides reaching man through his diet¹. For these reasons and because the major route of entry of radioiodine into the human diet is through milk, the rapid determination of iodine-131 in this foodstuff is important.

A number of authors have described procedures for the rapid determination of iodine-131 in milk. One of the most common approaches is to assay this radionuclide directly in fluid milk by γ -spectrometry². A second method consists of adsorbing the iodine-131 on anion exchange resin followed by γ -counting³⁻⁵. Although only ionic forms of iodine are adsorbed by anion exchange resin, approximately 95 per cent of the iodine-131 content of milk is present as iodide, so that only a small error is involved. A third method has also been described in which the radioiodine, once adsorbed on anion exchange resin, is eluted from the resin and prepared for β -counting⁶.

On the basis of the second of these methods, a field technique has been developed for the rapid collection of iodine-131 from milk⁷. In this procedure, a small cartridge, containing anion exchange resin, is used for concentrating and separating this radionuclide from the other fission products in milk. Experience⁸ has shown that such resin has a very high capacity for adsorbing this radionuclide. For example, approximately 160-200 resin bed volumes may be passed through a given volume at a flow rate of up to 1 resin-bed volume per min and still yield a removal efficiency of 95 per cent. With the use of the cartridge, the method is simple, inexpensive, and applicable to both emergency and routine situations. The purpose of this article is to describe the recent application of this technique in the field on a trial basis.

The opportunity for the investigation was provided by the October 1964 nuclear test by the People's Republic of China which introduced fresh fission products (including iodine-131) into the atmosphere. This material, carried by winds and deposited on open pasture, led to contamina-

tion of milk supplies in several areas within the United States. The investigation reported here was conducted in the vicinity of Burlington, Vermont, where the cartridges were used to sample milk from the major dairy plants in that city. Samples from bulk-tank trucks arriving at milk-processing plants and from silo tanks in the plants were first taken and analysed as a test of the applicability of the cartridge technique to routine environmental monitoring. In a second phase, the application to more detailed surveillance, or research investigations, was evaluated by a more intensive sampling programme in which samples from individual cows on a farm with relatively high activity of iodine-131 were processed.

The type of ion exchange cartridge used (see Fig. 1) was a modification of a model developed at the Southeastern Radiological Health Laboratory⁷. The unit consists of a polyethylene vial containing approximately 40 ml. of strongly basic quaternary amine-type anion exchange resin, 20-50 mesh, chloride form, suspended in distilled water. Milk is introduced through a separatory funnel attached to the top of the cartridge, passed through the resin bed, and then out through ten 2-mm diameter holes drilled in the bottom of the vial (see Fig. 2). Tests have shown that a litre (the quantity used in this investigation) of fresh milk will pass through a cartridge in about 20-30 min, the rate of flow being mainly determined by the choice of resin size.

Fig. 1. Cartridge and mailing tube

Fig. 2. Cartridge set up for field use

Since some fluid milk samples were brought back to the laboratory for duplicate processing, the study permitted an investigation of the suitability of thimerosal⁹ as a preservative for samples awaiting analysis by this technique. Previous experience had shown that formaldehyde, the preservative at present used in samples collected under the Public Health Service's Pasteurized Milk Network¹⁰, binds radioiodine to the milk protein and thereby prevents its adsorption by anion-exchange resin¹¹.

Although 'spot' counting of some samples was performed in the field using a portable multichannel γ -spectrometer, all the data reported in this article were based on radioactivity determinations made on the resins in the laboratory. For this purpose, the resin containing the adsorbed iodine-131 was emptied into cottage cheese containers which were then counted on a solid cylindrical 4 in. \times 4 in. NaI(Tl) crystal, coupled to a multichannel γ -spectrometer. Subsequent to this work, a cartridge of smaller diameter has been developed at the Northeastern Radiological Health Laboratory which can be directly inserted into a well-type crystal for counting. It is believed that this approach will have two advantages, one being that the well-type crystal will yield a greater counting efficiency, and the second being that such samples can be readily adapted to counting procedures utilizing automatic sample changers.

As previously mentioned, initial application of the ion-exchange cartridge technique was to samples of fluid milk arriving at milk processing plants. These samples represented supplies from the various dairies in the area surrounding Burlington, Vermont, and a summary of the observed data on levels of iodine-131 is shown in Table 1. As will be noted, the average concentration of this nuclide in the ten 1-l. samples, weighted according to the produc-

† Samples A₁, A₂, and A₃ all came from a single plant but were drawn from three different silo tanks. The same is true for samples B₁ and B₂.

tion of the given plant, was 38 pc./l. On this same date, the iodine-131 concentration in the composite Pasteurized Milk Network sample, collected at this same location and analysed in liquid form (3.5 l.) by γ -spectrometry³, was 31 pc./l. Since the counting error for each of these measurements was \pm 10 pc./l., the two results are in agreement.

To evaluate the acceptability of thimerosal as a preservative, additional samples were collected from three different tank trucks arriving at one of the larger plants serving this area. The preservative (3 ml. of a 10 per cent aqueous solution of thimerosal per litre of milk) was added to the samples in the field and they were then returned to the laboratory where 3.5 l. portions were analysed for iodine-131 by γ -spectrometry and 1-l. volumes were passed through the cartridges for analysis by the ion-exchange technique. Data on the concentrations of iodine-131 determined by the two methods are shown in Table 2. Again, considering the counting error in each of the reported values, the agreement in the data is acceptable.

Subsequent to these two investigations, a number of milk samples were obtained from individual cows at a dairy farm in Williston, Vermont. One-litre portions of most of these were passed through ion-exchange cartridges in the field, and additional 1-l. portions (some preserved with thimerosal and some not) were brought back to the laboratory where they, in turn, were also passed through similar cartridges 1-5 days later. All resins were then counted under identical conditions and a summary of the data for the three sets of samples is shown in Table 3.

Data for the eleven samples which were processed with and without preservative are presented in Fig. 3. The correlation coefficient for these data was 0.90. The close agreement in the values confirms the acceptability of thimerosal as a preservative and indicates that the processing of samples can be handled in the field with results

comparable with the more favourable conditions of the laboratory. The data also show that no chemical changes sufficient to affect the results occurred during the 1-4 days that the samples stood while preserved with thimerosal. Data for the fourteen samples processed both in the field and in the laboratory are shown in Fig. 4. Here the data had a correlation coefficient of 0.68. Except for three samples, not containing thimerosal, the data conformed to the expected relationship within the counting errors. Although not confirmed, it is possible that the lack of agreement in the data for these three samples was largely due to insufficient control of the milk flow-rate in the field. It is also possible that the cartridges were allowed to drain dry prior to initiation of the flow of milk, thus permitting short-circuiting of the fluid through the column. As will be noted, the samples processed in the laboratory yielded much greater concentrations of iodine-131 which tends to confirm one or both of these possibilities.

Of interest in Table 3 is the range of values of iodine-131 in the milk from the individual cows at the dairy. All

Fig. 3. Relationship between the observed iodine-131 concentrations in preserved and unpreserved milk. ●, Both samples processed in the laboratory; ○, one sample processed in the laboratory and one in the field.

cows in the herd were of the same breed (Holstein) and had been on open pasture until 3 days before samples of milk were taken. Even so, the data show that the levels of iodine-131 in the milk samples varied by a factor of ten. Two conditions possibly contributing to this wide variation were: (a) the proportion of supplemental (stored) feed consumed by each cow while still on open pasture; (b) the fact that the biological half-life of iodine-131 is shorter than the 3 days the cows had been off pasture. For this reason, the precise length of time the individual cows had been indoors before the milk samples were collected could be important. Attempts to correlate the individual radionuclide-levels with the age of the cows or the time of lactation were unsuccessful.

The major advantages of the use of ion-exchange cartridges are their simplicity and low cost. One complete field model, as shown in Fig. 1, costs approximately 3.00 dollars and all components can be used many times. The iodine-131 can be stripped from the resin with 2 N hydrochloric acid and the resin reconditioned with 2 M sodium chloride⁸. If the resin is washed clean with water after use, it can be used five or ten times (without exceeding the exchange capacity), provided the previously adsorbed iodine is allowed to decay. Where samples have to be sent to a centralized or regional laboratory for counting, there is a considerable saving in shipping cartridges rather than the 1-gal. milk samples normally required for determination of iodine-131. Because 1 l. (~1 quart) of milk is adequate for most determinations using the cartridges, there is also a saving in the amount of milk required for analysis.

In contrast to the procedure followed in this investigation, it is possible that the cartridges could be shipped in advance to a field location for use and then returned to a laboratory for counting. Since one funnel could be used to pass samples through a number of cartridges, once several funnels had been provided at a given sampling location, they could be retained there for use as required. Since iodine is the only radio-element separated from milk by anion resin, it would also be feasible to conduct entire studies of this type in the field. Under such conditions, counting could be carried out using a well-crystal scintillation detector and a suitable scaler. At higher levels, however, such as those contemplated under emergency conditions¹, measurement of the iodine-131 activity on the cartridges could be undertaken in the field with a simple Geiger-Müller survey meter.

On the basis of this study, it can be concluded that the ion exchange cartridge is an effective means for field sampling of iodine-131 in fluid milk. Because of the simplicity of the method, it appears especially advantageous wherever it is necessary to collect large numbers of samples.

We thank Dr. H. L. Wildasin and F. Norton and M. Lamson of the H.P. Hood Milk Co. for their co-operation in arranging the collection of the samples, W. I. Carr and B. Barrows of the Dairy Division, Vermont State Department of Agriculture, for their assistance in arranging the investigation, and E. J. Baratta, K. C. Lamson, and P. R. Groulx of the Northeastern Radiological Health Laboratory for assistance in collecting and analysing the samples and resulting data.

EXAMINATION OF A POLYSACCHARIDE FLOCCULANT AND FLOCCULATED KAOLINITE BY ELECTRON MICROSCOPY

By DR. ARNOLD AUDSLEY and ANITA FURSEY

National Physical Laboratory, Teddington, Middlesex

THE scope of the electron microscope as a tool in polymer science has recently been extended by Richardson¹, who has shown that individual molecules of amorphous polymers may be isolated by spraying a dilute solution of the polymer, in the form of fine droplets, on to a suitable supporting film. Polyacrylamide sprayed from an aqueous solution showed a unique, highly fibrous structure; the finest filaments were believed to be individual molecular chains. It is reasonable to assume that this structure is a replicate of the molecular configuration in aqueous solution. When controlled quantities of precipitant were added to the solution the molecules were isolated in the closely-coiled configuration and this enabled molecular weights to be determined by direct measurement.

Richardson's methods¹ have been applied in an investigation of the flocculation of suspensions of solids by organic polymers. In this Laboratory the electron microscope has been used both to examine a polysaccharide flocculant and to study the structure of polymer adsorbed on the surface of kaolinite particles.

Suspensions of ground minerals such as are encountered in hydrometallurgy may be flocculated by the addition of trace quantities of certain organic polymers, notably polyacrylamide and naturally occurring polysaccharide-type materials, of which guar, the ground endosperm of seeds from the legume *Cyamopsis tetragonolobus* shows the most strongly developed properties. A limited amount of evidence is available² to show that when suspensions are flocculated the particles are bonded together by adsorbed polymer molecules. If this is correct it may be assumed that rigid, linear polymers of high molecular weight will be the most efficient flocculants.

The major polysaccharide constituent of guar is a galactomannan of the structure³:

In the course of the present work the pure galactomannan was extracted from samples of commercial guar flocculant, fractionated from ethanol/water mixtures and isolated in the form of long white fibres. A middle fraction was used for all the experimental work (found: C—44.07 per cent, H—6.16 per cent, N < 0.1 per cent, P—0.011 per cent, $[\alpha]_D^{25} = 61.9^\circ$. Calc. for $C_{18}H_{30}O_{15}$, C—44.45 per cent, H—6.22 per cent).

The pure galactomannan contained 14.5 μg boron/g and it is probable that a trace of borate had been added

by the manufacturer to improve the flocculant properties of the polymer since it is known that when other polymeric flocculants are lightly cross-linked by suitable reagents a flocculant of greater efficiency is obtained^{4,5}. Borate ions are known cross-linking agents for polysaccharides which contain adjacent hydroxyl groups in the *cis* position. A pure galactomannan prepared from an untreated guar seed contained only 4.1 μg boron/g. It showed a lower value of the limiting viscosity number ($[\eta]$) than the borated sample (typical values of $[\eta]$ were 10.2 and 19.0 dl./g respectively) and by comparison it was an inferior flocculant of kaolinite suspensions. The borated polymer was used in the subsequent work because of its superior flocculant properties.

Solutions of the galactomannan were prepared by shaking the finely-ground solid with water in a nitrogen-filled ampoule for 16 h. A suitable quantity of solution was placed on an evaporated carbon film using both droplet and spray techniques and the polymer molecules shadowed with gold/palladium alloy at a height-to-shadow ratio of 1:4 before examination by electron microscopy. A very clean carbon film was important for this work as some particles produced during carbon evaporation were similar in size and shape to the polymer droplets under examination. To distinguish between the polymer and extraneous particles produced during the film preparation, the evaporated carbon was shadowed with gold palladium before any polymer was added and then turned at right angles before reshadowing. This meant that polymer particles had only one shadow on the final electron micrograph and any impurities present on the original evaporated carbon had two shadows perpendicular to one another.

Galactomannan deposited from an aqueous solution showed a similar fibrous structure to that of polyacrylamide¹. The structure was demonstrated when a droplet of a 0.1 per cent solution of the polymer was evaporated on a carbon film at normal temperature and pressure and shadowed, as described, before examination. Fig. 1 shows

Fig. 1. Fibres of polysaccharide from evaporated aqueous solution. Scale, 1 μ

a typical electron micrograph. The smallest diameter of fibre seen on a number of pictures was 0.004μ . These fibres are probably aggregates containing several molecular chains.

It is noteworthy that organic polymers of such widely differing chemical types, namely, polyacrylamide and a polysaccharide such as galactomannan, should show such close similarity in their molecular configuration in aqueous solution. It is logical to associate the fibrous structure of these polymers with their high limiting viscosity numbers (typical values of $[\eta]$ for aqueous solutions of polyacrylamide and galactomannan were 20.0 and 19.0 dl./g respectively) and their strong flocculant properties.

When a suitable precipitant (ethylene glycol) was added to a dilute aqueous solution of galactomannan and the mixture sprayed on to a carbon film, the appearance of the polymer changed and under appropriate conditions individual molecules were isolated in a partially collapsed oblate spherical configuration. A very dilute solution (10^{-2} per cent) of the polymer was necessary and it was applied to the carbon film in the form of a very fine spray with a 'Vaponefrin' nebulizer. Ideally this method may be used to determine the molecular weight distribution of the polymer¹, but in the limited time available it was not possible to find reproducible conditions in which all the molecules were in the fully collapsed spherical configuration which is necessary if the method is to be applied. An electron micrograph is shown in Fig. 2. It is apparent that the sample is still highly polydisperse and the original fractionation from aqueous solution was not efficient. In a system of this degree of polydispersity, it may be impossible to ensure that all the polymer molecules exist in the fully collapsed spherical configuration irrespective of polymer size.

A sample of kaolinite which had been flocculated with galactomannan was then examined by electron microscopy. If flocculation is due to polymer bridging, the orientation of the polymer chains in proximity to the particle surface might be observable by electron microscopy, assuming that the polymer structure is not completely destroyed when the sample is dried.

The flocculated solid was freeze-dried, dispersed on a supporting film and shadowed with gold/palladium alloy. The electron micrograph (Fig. 3) shows clearly the structure of the polymer in proximity to the kaolinite surface. A diagrammatic representation of the most prominent features is shown in Fig. 4. At 120,000 magnification some

Fig. 2. Particles of polysaccharide from sprayed water/ethylene glycol solution. Scale, 1μ .

Fig. 3. Kaolinite flocculated with polysaccharide. Scale, 0.5μ .

Fig. 4. Flocculant polysaccharide fibres shown diagrammatically

of the shadowed fibres attached to the kaolinite particles had a parallel stranded structure along their surface suggesting that they were composed of an aggregate of polymer chains. It was not possible to measure the diameter of the polymer fibres attached to the kaolinite surfaces with accuracy, but in general these appeared to be approximately 0.01μ diameter, which corresponds to a cross-sectional area about one order of magnitude larger than that of the smallest fibres seen on evaporation of an aqueous solution of the polymer.

This work provides strong evidence in favour of the polymer bridging theory of flocculation. The potential flocculant properties of both polyacrylamide and galactomannan may be correlated with their high limiting viscosity numbers and with their highly fibrous structure in solution, a structure which is retained to some extent after the polymer has been adsorbed on the surface of the solid.

EFFECTS OF HYDROCORTISONE SUCCINATE ON THE COMPLEMENT SYSTEM

By DR. HENRY GEWURZ*, PAUL R. WERNICK, DR. PAUL G. QUIE† and PROF. ROBERT A. GOOD‡

Pediatric Research Laboratories of the Variety Club Heart Hospital, University of Minnesota, Minneapolis

AMONG immunosuppressive agents, few have been as useful clinically as the adrenal steroids and few have been so little understood pharmacologically. Perhaps the most provocative of the recent findings on the activity of steroids have been the demonstrations that these drugs are capable of 'stabilizing' lysosomes *in vivo* and *in vitro*¹⁻⁸ and of protecting red cells against both immune and non-immune lysis *in vitro*, usually interpreted as an effect on the cell membrane⁹⁻¹³.

The findings reported here indicate that the capacity of hydrocortisone to inhibit immune haemolysis is largely dependent on interaction with the fluid phase constituents of complement-containing sera rather than with cell membranes directly.

In these investigations hydrocortisone succinate powder (kindly supplied as 'Solu-cortef' by the Upjohn Co.), free of contaminating reagents, was dissolved in an isotonic gelatine-veronal-saline buffer (GVB) with supplemental Ca^{++} and Mg^{++} (ref. 14) rather than in the accompanying anticomplementary diluting fluid, and the salt concentration adjusted to isotonicity; pH was 7.4. Sodium succinate, in the concentration present in the steroid powder, was not anti-complementary.

The activity of guinea-pig C' was tested by observing the rate and extent of lysis of sheep red cells sensitized with rabbit antibody (Sh EA). 0.5 ml. of a C' dilution was pre-incubated with 0.5 ml. of a hydrocortisone dilution at 37° or 0° C for various time-intervals. 1 ml. GVB and 0.5 ml. Sh EA (1×10^8 /ml.) were added and the mixture incubated for 60 min at 37° C. Time for complete haemolysis was recorded; if complete haemolysis did not occur within 60 min, the tubes were centrifuged and the 50 per cent lysis end point estimated visually. Hydrocortisone concentrations are expressed in terms of amounts present in the 1.0 ml. pre-incubation mixtures; final concentrations in the lytic step are two-fifths of this amount. The pool of guinea-pig serum used had a titre of 228 $C'H_{50}$ /ml. in the assay described by Osler *et al.*¹⁵, the reference units ('standard units') used in this report, and a titre of 1,792 $C'H_{50}$ /ml. in the assay system already described here, which is based on methods described by Nelson¹⁶.

Hydrocortisone was found to be an inhibitor of guinea-pig C' if certain conditions were met. The concentration of hydrocortisone, the time of pre-incubation, and the temperature during pre-incubation all played a part in the inhibition of a given amount of C' . The effect of varying concentrations of hydrocortisone on a fixed amount of C' during a fixed incubation period is shown in Fig. 1: concentration and degree of inhibition were directly correlated. Pre-incubation of low concentrations of hydrocortisone with C' was necessary to achieve inhibition; thus, while hydrocortisone in the range of 25 mg/ml. gave complete inhibition of 22.8 $C'H_{50}$ without pre-incubation, a pre-incubation period was required for lower concentrations.

As the pre-incubation period with a given hydrocortisone concentration (less than 25 mg/ml.) was increased, we noted a proportionate increase in the resultant inhibition of haemolysis (Fig. 2). Pre-incubation at 0° C was also

effective, but much greater intervals were required to achieve similar levels of inhibition.

There were other indications that the steroid effects were directed against the fluid phase constituents rather than against the cell membrane. Pre-incubation of hydrocortisone and sensitized cells before addition of complement, or pre-incubation of hydrocortisone before addition of sensitized cells and complement, gave minimal and no augmentation of inhibition, respectively. When a fixed amount of hydrocortisone was pre-incubated under standardized conditions with varying amounts of complement, the degree of inhibition varied with the amount of complement, again suggesting that fluid phase constituents rather than the size of the sensitized cell population determined the degree of haemolysis (Table 1).

6-Methyl prednisolone ('Solu-medrol', kindly supplied by the Upjohn Co.) was found to be significantly more effective than hydrocortisone in exerting this inhibition

Fig. 1 Effect of hydrocortisone concentration on the inhibition of guinea-pig complement *in vitro*

Fig. 2. Effect of length of pre-incubation period at 37° C and 0° C on hydrocortisone-induced inhibition of guinea-pig complement *in vitro*

Table 1. EFFECT OF PRE-INCUBATION OF A FIXED CONCENTRATION OF HYDROCORTISONE (0.25 mg/ml.) WITH VARYING AMOUNTS OF C' FOR 60 MIN AT 37° C

No. of EA	No. of $C'H_{50}$ (standard units)	Inhibition (%)
5×10^7	5.7	0
5×10^7	2.9	50
5×10^7	0.7	100

when equimolar quantities were tested in identical assays (Fig. 3), indicating that more than simply the steroid structure of this molecule is responsible for the inhibitory effect on C' .

From these experiments we conclude that hydrocortisone exerts a concentration-, time- and temperature-dependent inhibitory effect on guinea-pig C' in the fluid phase. In another series of experiments, a similar effect was seen on human C' .

In the next set of experiments we sought to determine which complement components were inhibited by the steroids. Thus, 22.8 $C'H_{50}$ was pre-incubated in 12.5 mg/ml. hydrocortisone for a 2-h interval at 37° C (sufficient to achieve complete inhibition). This mixture, together with parallel control mixtures of guinea-pig C' and of hydrocortisone with normal saline solution with appropriate metals added, was dialysed against isotonic saline supplemented with calcium and magnesium, for a 24-h period. Effectiveness of the dialysis was assessed by determination of optical density in a Beckman DU spectrophotometer at 240 and 280 m μ ; on this basis, more than 98 per cent of the hydrocortisone initially present had been removed from the mixtures. This afforded opportunity to assay for each of the four classical C' components in a system containing amounts of hydrocortisone insufficient to have caused inhibition in the original pre-incubation mixture. $C'1$, $C'4$ and $C'2$ activities were tested using the assays described by Nelson¹⁸, and each was found to be markedly decreased in the hydrocortisone-treated sera; overall $C'3$ activity was also markedly decreased, using the assay described by Osler *et al.*¹⁷. Further, hydrocortisone introduced at any step in the interaction of the classical four C' components, that is, after formation of the intermediates $EAC'1$, $EAC'1,4$ or $EAC'1,4,2$ had been allowed, still was inhibitory. Thus, hydrocortisone seemed to inhibit each of the four classical complement components.

In order to test the inhibitory power of hydrocortisone on non-lytic C' -dependent functions, immune adherence activity was tested using the assay system described by Nishioka¹⁸. 12.5 mg/ml. hydrocortisone inhibited completely the immune adherence potential of a pool of guinea-pig C' which otherwise showed titres greater than 1/5,000.

The striking inhibition which corticosteroids exert on C' in the fluid phase, though suggested by various *in vivo* observations in experimental animals¹⁹⁻²² and man^{23,24}, had not to our knowledge been realized *in vitro*. Simonsen¹⁹ studied the effect of cortisone acetate on guinea-pig complement *in vitro*, but under his experimental conditions observed no effect. Fischer *et al.*^{10,11} clearly showed that prednisolone had a dose-dependent inhibitory effect on the immune haemolysis of red cells, but attributed this to effects on the red cell membrane. Jennings and Taylor¹³ found that hydrocortisone had a profound inhibitory effect on the immune haemolysis of sheep red cells, and addressed themselves to identification of the site of this inhibition. They found that pre-incubation of C' and hydrocortisone did not augment the inhibition; dialysis of an initially inhibited mixture of sensitized cells, C' and hydrocortisone against saline eventually resulted in lysis, presumably after the hydrocortisone had dialysed away; and washing hydrocortisone away from a suspension of sensitized cells left them susceptible to subsequent lysis by additional C' . These experimental results, together with the evidence for the capacity of steroids to protect cells against non-immune lysis, led these investigators to conclude that hydrocortisone was not

Fig. 3. Comparison of the effect of equal concentrations (6.25 mg/ml.) of hydrocortisone and 6-methyl prednisolone on varying amounts of guinea-pig complement in the pre-incubation mixture
---, Control; ···, hydrocortisone; —, 6-methyl prednisolone

exerting its anti-haemolytic effect directly on C' , but rather on the cell membrane, presumably by preventing attachment of one or more components of C' .

Our own results indicate that hydrocortisone and 6-methyl prednisolone can interact directly with the guinea-pig serum, with consequent inhibition of the C' components. Osler, in a subsequent personal communication, had observed a similar effect. The use of prolonged pre-incubation periods of the steroid with complement at physiological temperatures, with appropriately selected concentrations of steroids and amounts of complement, makes this interaction more apparent, and, further, suggests that it may occur *in vivo* with therapeutic concentrations of steroid by selective accumulation at appropriate sites, though at present the amounts of steroid used in our experiments make us cautious about extrapolating these data to immunological phenomena in health and disease. Since each of the classical C' components (known to be or to include α - and β -globulins) seems to be inhibited, and certain globulins are known to bind cortisone preparations, as reviewed by Gray *et al.*²⁵ and Doe *et al.*²⁶, we assume that a direct interaction with the C' globulins is occurring; but indirect effects are also a possibility. We believe that activation with consequent consumption of the C' components is unlikely because hydrocortisone exerts its inhibitory effects even when added late in the kinetic reaction sequence, that is, even after the $EAC'1,4,2$ complex had been formed. Further, preliminary results indicate that, paradoxically, concentrations of hydrocortisone not inhibitory to the C' in the test system inhibit the anti-complementary effects of aggregated globulins when sensitive assay systems are used. Since hydrocortisone serves to protect against, rather than to augment, the activation and subsequent consumption of C' by aggregated γ -globulin, we doubt whether it provides a surface on which the globulins can be aggregated as chylomicrons did in the studies of Quie and Hirsch²⁷. The characteristics of these interactions of hydrocortisone with antibody and complement globulins are being further investigated.

Immune adherence was tested in the presence of hydrocortisone to see if the steroid was effective in inhibiting C' -dependent functions in which lysis was not the end-point, functions in which potential 'membrane stabilization' would not be as prominent a factor. The inhibition noted was in accord with the conclusions of Packer *et al.*²⁸, who had found various corticosteroid preparations to inhibit immune erythrophagocytosis by human polymorphonuclear leucocytes *in vitro*. The mechanism of this inhibition was not studied by these investigators, but since immune erythrophagocytosis has been shown by Nelson¹⁸ and Gerlings-Petersen and Pondman²⁹ to be C' -dependent, and Nelson¹⁸ has shown the same C' com-

ponents to be involved in both erythrophagocytosis and immune adherence (his $C'1$, $C'4$, $C'2$ and $C'3c$ of the nine C' components he found to be necessary in order to obtain immune haemolysis) we would postulate that Packer *et al.* were observing the effects of C' inhibition by corticosteroids.

Many other of the effects of steroids, both *in vivo* and *in vitro*, may find partial or total explanation in the direct (on the C' components) and indirect (on aggregated γ -globulins) effects of these compounds on the C' system, including those ranging from the anti-inflammatory and anti-phagocytic to the still unexplained beneficial effects of steroids in haemolytic anaemias, systemic lupus erythematosus, plasma cell hepatitis, rheumatoid arthritis and transplantation rejections.

In summary, hydrocortisone was found to exert an inhibitory effect on the C' activity of guinea-pig serum in the fluid phase, an effect which was dependent on time, temperature and concentration. Each of the classical four C' component activities was inhibited, as was immune adherence activity.

CORRELATION BETWEEN UNIT ACTIVITY AND SLOW POTENTIAL CHANGES IN THE UNANAESTHETIZED CEREBRAL CORTEX OF THE CAT

By A. D. J. ROBERTSON

Autonomics Division, National Physical Laboratory, Teddington, Middlesex

MANY authors have described more or less consistent relationships between sensory evoked potentials and unit firing in the cerebral cortex¹, and Fox and O'Brien have recently shown that: "Computer compilation of the probability of firing of a single cell in cat cortex following a physiological sensory stimulus (somatic or light flash) indicates that the frequency distribution of the firing of a single cell closely corresponds to the average waveform of the evoked potential recorded from the same microelectrode"². Good correlations are also found between cell firing and synchronized slow waves such as spindles³. In general, surface positive potential shifts correspond to an increased probability of unit firing, as would be predicted from reasonable assumptions about cell shape and orientation. Rusinov demonstrated that surface positive polarization could make large areas of cortex excitable to hitherto indifferent stimuli⁴, and Morrell has repeated this and investigated the effect at the unit level. Polarization may change the rate of learning, as shown in conditioning experiments⁵. The great interest in potential fields and their effects on cortical activity (see John *et al.*⁶ for a recent discussion) makes it even more important to discover the relation between unit firing and slow potential changes in the unanaesthetized, spontaneously active brain. No clear-cut correlations have been reported and there has been some controversy as to whether any correlation exists at all⁷. At first sight the situation is more complex than in refs. 1-3, as the electrocorticogram (ECG) is desynchronized and must have many unrelated components from different sources within the central nervous system. The results in this article show that correlations may be found in the un-

anaesthetized cortex when averaging techniques are used in analysis.

Twelve cats were used in these experiments. After the mid-brain had been sectioned at the mid-collicular level under ether anaesthesia the animals were allowed to recover from the anaesthetic, but were paralysed with 'Flaxedil' (gallamine triethiodide) to prevent muscular movements which might interfere with the recording. A large area of cortex was exposed on one side and covered with warm mineral oil. Extra-cellular recordings of unit activity were made using glass micro-pipette electrodes with internal tip diameters of 1-5 μ and resistances between 0.2 and 0.8 M ohms, filled with 9/10 saturated sodium chloride solution. The micro-electrode was referred to an electrode on the cortical surface immediately above. This consisted of a cotton wick impregnated with saline-agar protruding from a glass tube filled with the same medium. Contact with the conducting medium of both electrodes was made with Ag-AgCl wires. The preparation was grounded through the mouth-piece of its head-holder. Two recording channels were used, one a.c.-coupled, the other d.c.-coupled. The d.c. signal was led to a modulator the output frequency of which varied between 2 and 10 kc/s and was proportional to the applied voltage. Both signals were stored on magnetic tape for later analysis of the results.

The experiments simply involved the recording of the spike activity of cortical cells and the simultaneous slow potential changes between the cells and the cortical surface. Several authors have made similar recordings referring the surface electrode to a distant point⁸; but in the experiments reported here it was felt that the potential

developed across the cortex would be more significant, particularly as most of the cells recorded from it were in the layer of large deep pyramids 0.8–1.5 mm from the cortical surface⁹. No attempt was made to select cells from particular areas of the cortex, although most cells were in the median suprasylvian or lateral gyri.

Fig. 1 shows the result of an analysis, from a 4-min length of record containing 962 spikes, to find the relation between surface potential and spike frequency. On a semi-logarithmic plot this gives a fairly straight line. All cells so far examined (fourteen) show similar relations, but it is significant that even for cells so close together that their activity may be recorded from the same micro-electrode the relationship is not identical. This result supports the idea that each cortical cell has a different threshold to incoming excitation, perhaps as a result of its past 'experience'.

Smith and Smith have shown that the spontaneous activity of cortical cells may be considered as consisting of two components, one being 'bursts' of spikes separated by relatively short intervals, the other representing the longer intervals between these bursts¹⁰. The distributions of both types of interval approximate to randomness, but the short interval distribution is much the more stable. The long interval distribution can be changed by physiological or electrical stimulation and by polarization. These results led to the hypothesis that the long interval distribution represented a gating process, switching the cell on into its standard activity. As surface positive polarization (Bindmann *et al.*⁸) is known to increase the activity of underlying cells it seemed profitable to examine the relation between bursts of spike activity and surface positive potential shifts. Fig. 2 shows the results of such an analysis. The spike record is divided into bursts and inter-burst intervals using the criterion described in ref. 10. Similarly, the slow wave record is divided into periods spent above and below an arbitrary threshold. The degree of overlap of the two processes, that is, the correlation between them, is very much better than would be expected were they unrelated, but it is not perfect. (Perfect correlations can be seen in records from preparations anaesthetized with both barbiturates and volatile anaesthetics. In these cases there is good evidence that activity within the cortex, depending on transmission across many

Fig. 1. The relationship between spike frequency and the potential difference between the cell body and the cortical surface

Fig. 2. A is an idealized spike record divided in B into bursts and inter-burst intervals. C shows the periods during which the slow potential variations D between the cell body and cortical surface cross a threshold. The overlap between B and C gives the correlation between bursts and surface positive potential shifts. In one example bursts occupied 16.4 per cent of the record and potential excursions above 50 μ V surface positive occupied 33.4 per cent of the record. If the two were unrelated a 5.5 per cent overlap would be expected. In fact there was a 13.4 per cent overlap. That is, whereas 30.2 per cent of the bursts would be expected to overlap, 81.2 per cent of the bursts overlapped with surface positive potential shifts above the threshold.

synapses, is much reduced, giving rise to a simplified ECG with few high-frequency components—so that one would indeed expect a better correlation¹¹.)

Much recent work has provided a basis for the probabilistic relationship between single unit activity and slow waves described in this article¹². It seems likely that slow waves are more than the mere expression of complex unit activity below the cortical surface and may have important functions in controlling the excitability of cortical neurones. There are abundant widely distributed fibre systems which could provide an anatomical basis for such a function (Sholl, *op. cit.*). Furthermore, there are situations in which considerable slow wave activity is present without accompanying spike activity, for example in young animals before the maturation of cortical synapses and in anaesthetized animals¹³. A fuller discussion of these ideas and a more detailed presentation of results is in preparation.

BLOOD FLOW IN TURTLES

By FRED N. WHITE and GORDON ROSS

Departments of Physiology and Biophysics and Nuclear Medicine, University of California, Los Angeles

ALTHOUGH of great interest to the comparative physiologist, the circulation of the blood in reptiles has received little study. There is no information on blood flow in the great vessels, cardiac output or the factors affecting its distribution between systemic and pulmonary circuits in intact animals. This article reports the electromagnetic determination of blood flow in the aorta, subclavian and pulmonary arteries of intact unanaesthetized turtles and illustrates the instantaneous flow patterns in these arteries and also the changes resulting from temperature variation, respiration, and painful stimuli.

Turtles (*Pseudemys scripta*) weighing 2-3 kg were refrigerated for several hours at 5° C and then transferred to a tray of ice. A portion of the plastron (8 cm × 8 cm) was removed and 1-cm lengths of the arteries to be studied were separated from adjacent connective tissue. Flow was measured with the gated sine-wave electromagnetic flowmeter using non-cannulating probes^{1,2}. In some animals indwelling polyethylene catheters were inserted into an aorta and pulmonary artery for pressure determination. The excised plastron was then replaced and secured with stainless steel sutures and sealed with acrylic denture material. The flow probe cables and pressure leads were strapped to the carapace after removing the turtle from the ice tray. The investigations reported here were performed during the first 4-7 post-operative days, during which time the animal's behaviour was identical to that before operation. The turtles usually died within 10 days of operation and autopsy invariably showed a large blood clot at the operation site but no evidence of damage or obstruction to the arteries carrying the probes. Calibration was performed by allowing saline to flow from a gravity feed through the flow probes into a graduated cylinder. In some experiments, for example during forced diving, very low heart rates of 1-2 per min were observed. The portion of the flow trace immediately preceding one of these infrequent beats was considered to

represent zero flow and was used as the reference level for flow measurements.

Simultaneous pressures and flows in the pulmonary and subclavian arteries of a 3-kg turtle are shown in Fig. 1.

Fig. 2 shows the simultaneously recorded instantaneous flow contours of the left aortic arch, right aortic arch (distal to brachiocephalic artery) and left pulmonary artery at a heart rate of 26/min. The left aortic flow contour strikingly resembled the aortic flow pattern of mammals in showing a steep upstroke, a rounded summit, a less steep initial downstroke, and a prominent back flow phase. Right aortic arch flow, recorded distal to the brachiocephalic artery, was similar to that of the left arch except for the absence of a prominent back flow component. The subclavian flow pattern also resembled that of the left aorta. The initial back flow phase seen in Fig. 1 was an inconstant feature. Pulmonary flow commenced approximately 0.15 sec before aortic and the flow contour resembled that of the pressure. No pulmonary back flow was recorded. Flow in the pulmonary artery continued throughout the cardiac cycle whereas flow in the aorta occupied approximately 40 per cent of the cardiac cycle.

The effect of temperature on pulmonary flow is shown in Fig. 3. At 20° C and a heart rate of 30/min the combined stroke flow in the pulmonary arteries was 2.8 ml., giving a

Fig. 1. 3-kg unanaesthetized turtle. Upper trace, pressures in a pulmonary artery (p) and aorta (a) obtained from the same pressure transducer; middle trace, pulmonary flow, lower trace, subclavian flow. Heart rate, 32/min; aortic pressure, 30/25 mm mercury; pulmonary pressure, 27/10 mm mercury, stroke pulmonary flow, 1.2 ml; stroke subclavian flow, 0.12 ml.

Fig. 2. 2.5-kg unanaesthetized turtle. Simultaneously recorded instantaneous flow contours. Upper trace, right aorta (distal to brachiocephalic); middle trace, left aorta, lower trace, left pulmonary artery

Fig. 3. 3-kg unanaesthetized turtle. Effect of temperature on instantaneous pulmonary flow. Upper trace, 7° C, heart rate 7/min, stroke flow 2 ml., lower trace, 20° C heart rate 30/min, stroke flow 1.4 ml.

minute flow of 84 ml. At 7° C and a heart rate of 7/min, total stroke pulmonary flow was 4 ml., giving a minute flow of 28 ml. The increased stroke volume of 7° C occurs despite a reduction in average flow velocity because of prolonged duration of flow.

The respiration of turtles is irregular with long periods of apnoea interrupted by variable numbers of respiratory cycles. All turtles showed an increased pulmonary blood flow during periods of respiratory activity. In some animals the heart rate increased with respiration and bradycardia occurred during the apnoeic periods. Systemic flow changed little with respiration but was usually slightly reduced. In the example shown in Fig. 4, at the end of a period of apnoea lasting 2 min, the heart rate was 22/min. At the peak of the succeeding respiratory activity the rate had increased to 29/min, stroke pulmonary flow had increased 28 per cent while stroke subclavian flow had diminished by 6 per cent.

The effect of a painful stimulus is shown in Fig. 5. Pinching the tail caused a simultaneous reduction in subclavian flow and increase in pulmonary flow. Both aortic and pulmonary pressures increased. These

Fig. 5. 3-kg unanaesthetized turtle. Effect of painful stimulus. Upper trace, mean pressures obtained from the same pressure transducer: aortic (a); pulmonary (p); middle trace, mean pulmonary flow; lower trace, mean subclavian flow. Painful stimulus applied between arrows

changes are compatible with an increased systemic resistance causing more of the output of the incompletely divided ventricle to be diverted into the pulmonary circulation with corresponding reduction of systemic flow.

In addition to the work reported here the electromagnetic method of blood flow determination has proved valuable in an investigation of the circulatory changes produced by prolonged diving.

We thank Dr. Alexander Kolin for his interest in and support of the project and much helpful advice concerning electromagnetic flow measurement. This work was aided by grants from the U.S. National Science Foundation (GB 923) and the U.S. Office of Naval Research (233-38).

BINDING OF XENON TO HORSE HAEMOGLOBIN

By DR. B. P. SCHOENBORN

Medical Research Council Laboratory of Molecular Biology, Hill's Road, Cambridge

THIS article is a sequel to the recent report on the binding of xenon to sperm whale myoglobin¹. There it was shown by an X-ray diffraction analysis that a single atom of xenon binds to a specific site buried in the interior of myoglobin, in contact with one of the pyrrole

Fig. 1. Binding of xenon to haemoglobin as calculated from solubility measurements in 5 per cent haemoglobin solutions. The ratio of its solubility in water and in haemoglobin solutions is independent of temperature to within 5 per cent

rings of the haem group, with the haem-linked histidine, and with several other groups.

It has been found that during xenon anaesthesia² about 45 per cent of the xenon in blood is carried by haemoglobin³. Fig. 1 shows the affinity of xenon for horse methaemoglobin measured in aqueous solutions with a constant volume Barcroft type manometer.

Henry's law is obeyed in the range of pressure used (0.5–1.5 atm.). The fact that no saturation occurs suggests that there must be several xenon binding sites. The amount of xenon bound by reduced and oxyhaemoglobin was the same within 5 per cent as that bound by methaemoglobin.

Horse methaemoglobin crystals in 2 M ammonium sulphate solution at pH 7.0 were mounted in thin-walled quartz capillaries. The crystals were flushed with xenon before introducing some xenon-saturated mother liquid at one end, which was then sealed. To ensure high xenon occupancy, the gas pressure was increased to 2 atm. before sealing the other end. At higher pressures the capillaries tended to explode. The intensities of the *h0l*, *hk0* and *0kl* reflexions were collected to a resolution of 2.7 Å. After the usual corrections, difference-Fourier projections were calculated using the appropriate version of the general equation:

$$\Delta\rho(x,y,z) = \frac{1}{V} \sum_h \sum_k \sum_l (|F_{(hkl)}| - |F_p|) \exp(-2\pi i(hx + ky + lz) + i\alpha)$$

Fig. 2a. $\Delta\rho(x,z)$. Difference in electron density in projection on (010), 2.7 Å resolution

Fig. 2b. $\Delta\rho(x,y)$. Difference in electron density in projection on (001), 5.5 Å resolution

$|F_p|$ and $|F_{(x,y,z)}|$ represent the moduli of the structure amplitudes of the native haemoglobin and its xenon derivative respectively; $\Delta\rho(x,y,z)$ is the difference in electron density between the two compounds. The phase angles used were those for native horse haemoglobin which have been determined out to spacings of 2.7 Å for the centrosymmetric $h0l$ terms and of 5.5 Å for the non-

centrosymmetric $h\bar{k}0$ and $0kl$ terms, using isomorphous replacement⁴.

The difference electron density map of the centrosymmetric projection on (010) shows one slightly elongated peak per asymmetric unit. The projection on (001) shows two circular peaks per asymmetric unit at approximately the same x -co-ordinate as the single peak in the centrosymmetric projection, indicating that the elongated peak in the latter is made up of two superimposed peaks. The projections (Figs. 2a and b) provide the following fractional xenon co-ordinates:

$$x_1 = 0.23 \quad y_1 = 0.81 \quad z_1 = 0.10 \quad \text{occupancy} = 0.8$$

$$x_2 = 0.22 \quad y_2 = 0.20 \quad z_2 = 0.62 \quad \text{occupancy} = 0.5$$

In this space group (space group C2, unit cell dimensions: $a = 108.95$ Å, $b = 63.51$ Å, $c = 54.92$ Å, $\beta = 110^\circ 50'$) the asymmetric unit contains only half the haemoglobin molecule, that is, one α - and one β -chain, and by comparing the co-ordinates of the two peaks with the model of haemoglobin, it can be seen that one xenon atom must lie within the α sub-unit and the other within the β sub-unit. The location of the sites is quite different from that in myoglobin (Fig. 2b) and slightly different in the two chains (Figs. 3a and b). The xenon atoms are located inside the sub-units, but close (6 Å) to their external

Fig. 3. Location of xenon in (a) the α - and (b) the β -chain. The xenon atom lies buried underneath the GH corner which faces the reader, and nearer the AB corner than this view of the chains suggests. The xenon site in myoglobin is indicated by an x. (Drawing of the chain adapted by permission, from M. F. Eder, *Sci. Amer.*, 211, 5, November 1964)

surface between the *AB* corner and the *GH* corner and are approximately related by the pseudo-dyad axis of symmetry named dyad 1 by Cullis *et al.*⁴. However, the xenon atom in the α -chain lies nearer the *GH* corner and that in the β -chain closer to the *AB* corner. At first it might appear surprising that the xenon positions in the two chains are different from one another, and not the same as in myoglobin. The *AB* corners of the α - and β -chains differ in both the sequence and the number of residues they contain, giving rise to structurally different environments. The amino-acid sequences in the *GH* corners are also different, though here the two chains are of equal length. It should also be noted that the amino-acid sequences of myoglobin⁶ and haemoglobin are quite different. Any change in atomic distribution near a cavity could easily change the electronic interaction with xenon towards an energetically unfavourable state.

The exact analysis of the xenon sites will have to await determination of the haemoglobin structure at high resolution. On the basis of Perutz's tentative atomic model of haemoglobin⁷, the nearest neighbours of both xenon atoms are valine, leucine and phenylalanine. This complex is presumably stabilized, as in myoglobin, by dipole- and quadrupole-induced dipole and quadrupole moments and London interactions. A theoretical investigation by Kittel and Shore⁸ of xenon polarizability has shown that the quadrupolar (as well as the dipolar) polarizability is particularly high, thus favouring binding

in situations like this where one might not otherwise expect it. An analysis of the change in protein-bound water⁹ between haemoglobin and the haemoglobin-xenon complex by a microwave technique showed an increase of protein-bound water, due to the presence of xenon. Any attempts to demonstrate this directly by X-ray methods must also await the final analysis of haemoglobin at high resolution, but changes in the charge distribution caused by xenon atoms located close to the surface of the molecule could account for the increase in bound water.

I thank Dr. M. F. Perutz for his advice and use of his structural data of haemoglobin.

POLYMORPHISM AND MITOCHONDRIAL ACTIVITY IN SLEEPING SICKNESS TRYPANOSOMES

By DR. KEITH VICKERMAN

Department of Zoology, University College, London

THE trypanosomes of human sleeping sickness, *Trypanosoma gambiense* and *T. rhodesiense*, are at all times morphologically indistinguishable from *T. brucei* of wild game and domestic animals in Africa, and can be regarded as genetic variants of *T. brucei* with the ability to infect man. These flagellates, previously designated the *T. brucei* sub-group, and now assigned to the sub-genus *Trypanozoon* by Hoare¹, differ from other tsetse-borne trypanosomes in two important features: (1) They undergo a complex life-cycle, involving changes in form (Fig. 1), in the tsetse fly (*Glossina* spp.), developing first in the midgut and later in the salivary glands. (2) In the bloodstream of the natural mammalian host they show a wide variation in form, ranging from long slender flagellates with a free flagellum at the anterior end, to short stumpy forms with no free flagellum (Fig. 1).

Because of this second character these trypanosomes are often referred to as the 'polymorphic' trypanosomes, but this description is misleading. The morphological variation is continuous, biometrical investigations² giving no support to the idea that several distinct forms co-exist in the bloodstream, and any implication of a genetic basis to this multiplicity of forms was ruled out by Oehler³, who showed that polymorphism can persist in clone infections. Strictly speaking, the flagellates are pleomorphic, but the change in form appears to follow a regular pattern in the course of infection, for the bulk of available evidence shows that slender forms are most abundant when the parasitaemia is rising, whereas short, stumpy forms preponderate when the number of flagellates in the blood is falling³⁻⁵; slender forms appear to transform into stumpy forms^{7,8}.

The cause and adaptive significance of polymorphism in *Trypanosoma brucei*-like trypanosomes are obscure. It has been suggested that the host's immune response

stimulates the transformation from slender to stumpy forms^{7,8}. In chronic infections the number of trypanosomes in the blood fluctuates, and it appears that each peak of parasitaemia represents a different antigenic variant⁹, the trypanosomes changing their antigens to avoid the host's immune response. If host antibodies do induce the

Fig. 1. Diagram of life-cycle in *Trypanosoma brucei*-like trypanosomes. In the mammalian bloodstream slender forms divide or transform into stumpy forms via intermediate forms. Stumpy forms, on entering the tsetse fly, transform into elongate midgut flagellates which, after multiplication and migration in the fly, multiply as crithidial forms in the salivary glands. The metacyclic forms which arise from crithidias are infective to the mammalian host when injected with the fly's saliva.

morphological transformation, then the stumpy forms may represent the forms which are changing their antigens; but as yet there is no direct evidence that this is so. Slender forms may be present at all stages in the infection, and Ashcroft has suggested that these forms might undergo antigenic change to give rise to the relapse strain⁷.

Robertson⁸, and later Reichenow¹⁰ and Wijers and Willett¹¹, observed that, should infected blood be ingested by a tsetse fly, it is the stumpy, rather than the slender, trypanosome which develops in the midgut to initiate the cycle in the fly. Corroborating evidence for this comes from observations on the behaviour of polymorphic trypanosomes maintained by syringe passage in laboratory animals. After several passages the trypanosomes become monomorphic, slender-like forms only being found in the blood^{12,13}. This loss of polymorphism is accompanied by loss of transmissibility by tsetse flies¹³. *Trypanosoma evansi* represents the natural counterpart of these 'non-transmissible' strains. It is morphologically indistinguishable from monomorphic *T. brucei*, and Hoare¹⁴ has suggested that it arises from *T. brucei* when this flagellate is carried outside the tsetse belt by camels, and transferred from host to host by biting flies (for example, *Tabanus*) acting like syringes.

The behaviour of bloodstream trypanosomes on entering the fly is paralleled by their behaviour when inoculated into suitable culture media. Only strains which will infect *Glossina* will establish themselves in culture on blood agar media¹⁵, and the forms assumed in culture are morphologically and physiologically identical with those found in the fly midgut¹⁶.

At present, then, polymorphism in *Trypanosoma brucei*-like trypanosomes appears to be associated with cyclical transmissibility, in that its loss is accompanied by failure to develop in the midgut of *Glossina* and reluctance to be cultivated *in vitro*, but the reason why these characters should be linked is not understood.

Morphogenesis in *Trypanosoma brucei*. In developmental terms, the life-cycle in Protozoa can be envisaged as a series of morphogenetic responses on the part of competent cells to certain environmental changes. The cellular basis of this morphological transformation from one stage to the next in the trypanosome life-cycle is not known, but ultrastructural and biochemical investigations are beginning to provide some clues. Seen with the light microscope, the morphological changes in *Trypanosoma brucei* are extremely simple. Apart from the relative changes in length and width of the body, and length of the flagellum with respect to body-length, the most noticeable changes are seen in the spatial relationships of the kinetoplast, at the base of the flagellum, to the nucleus and to either end of the flagellate's body. In bloodstream forms the kinetoplast lies close to the posterior end of the flagellate; in the fly midgut forms it lies posterior to the nucleus but some distance from the posterior extremity of the flagellate. In crithidial forms attached to the walls of the salivary gland the kinetoplast lies immediately anterior to the nucleus, while in the metacyclics which develop from them the kinetoplast is once again at the posterior end of the flagellate (Fig. 1).

I have suggested that adaptive changes in the chondriome of *Trypanosoma brucei* and allied species might be at least partly responsible for cyclical transformation¹⁷. Investigations with the electron microscope have shown that the kinetoplast in trypanosomes is the DNA-containing part of the chondriome. The structure at the base of the flagellum which is stained by Romanowsky techniques and gives a positive Feulgen reaction¹⁸ is seen with the electron microscope as a fibrous disk embedded in a mitochondrion¹⁹⁻²¹ (Fig. 2). The kinetoplast has been known to stain with Janus green B for some time²². There is mounting evidence that DNA is a widespread component of mitochondria²³; the large amount detectable in the trypanosome kinetoplast may indicate the presence of multiple chondriome DNA units²⁴.

An ultrastructural comparison of monomorphic bloodstream forms of *T. brucei* with fly midgut forms (as obtained in culture) showed that the appearance of the chondriome is very different in the two¹⁷. In bloodstream forms a mitochondrial tube, with scarcely any cristae, pursues a sinuous course from the kinetoplast to the anterior end of the flagellate, and a similar, but very short, tube may extend to the posterior end. The midgut forms, on the other hand have an extensive network of mitochondrial tubes at the anterior end and a prominent post-kinetoplastic chondriome, the kinetoplast in these forms lying some distance from the posterior extremity of the flagellates. Comparative respiratory investigations of these forms give meaning to this structural difference. In monomorphic bloodstream forms, glucose is respired only as far as pyruvate which is excreted, as a functional Krebs cycle appears to be wanting in these forms^{25,26}; the flagellates are almost unique in that their energy is derived from aerobic glycolysis. Although large amounts of oxygen are consumed by the flagellates, terminal respiration is independent of cytochrome pigments, which are absent, and is effected by an L- α -glycerophosphate-oxidase-L- α -glycerophosphate dehydrogenase system²⁷⁻²⁹; Ryley³⁰ has recently produced evidence that this alternative terminal respiration system is housed in distinct cytoplasmic bodies outside the chondriome. The fly midgut forms, however, respire their pyruvate completely and appear to have conventional oxidative phosphorylation linked to a Krebs cycle and cytochrome carrier system^{26,27,31,32}.

From comparative ultrastructural and biochemical investigations it would appear that the chondriome of the bloodstream trypanosomes is inactive, as Krebs cycle enzymes and cytochrome pigments, which are mitochondrial components, are absent. In the fly midgut, on the other hand, the trypanosome chondriome appears to be very active. On the basis of such investigations I suggested that the bloodstream trypanosome, on entering the fly, produced mitochondrial enzymes and a more extensive and active chondriome to enable it to switch its pattern of respiration to a more economical one in keeping with its new surroundings. I also suggested that adaptive proliferation of the posterior chondriome in particular resulted in the change in form, the new chondriome growing out from the kinetoplast, extending the posterior end of the trypanosome. In *Trypanosoma brucei*, then, adaptive mitochondriogenesis might explain the different positions adopted by the kinetoplast, and changes in size, which are an integral part of morphogenesis. A similar conclusion was reached for the transformations observed in the kinetoplastic flagellate *Leishmania donovani* by Rudzinska, d'Alessandro and Trager³³. It may be noted here that the microtubules, which spiral in a longitudinal direction beneath the entire pellicle of the trypanosome (Fig. 2), probably serve as a corset directing growth along the longitudinal axis of the flagellate. Microtubules are now known to be commonly associated with elongating cells³⁴.

Fig. 2. Diagram of structures involved in respiration, locomotion and transformation of *Trypanosoma brucei* (intermediate bloodstream form). Pellicular microtubules are shown only at the anterior end of the flagellate.

These ideas on the transformation of bloodstream forms entering the tsetse fly, however, neglected the fact that monomorphic bloodstream forms rarely, if ever, infect the fly, whereas the stumpy forms of polymorphic strains do; an important metabolic difference between slender (or monomorphic) and stumpy forms is implied, which confers a selective advantage on the latter, enabling them to develop into midgut forms in *Glossina*.

Mitochondrial activity in bloodstream trypanosomes. Most trypanosomes do not appear to show the extremes of respiratory behaviour encountered in the monomorphic bloodstream and fly midgut forms of *Trypanosoma brucei* as recounted here. Steinert³⁵, using NAD diaphorase as a mitochondrial marker, has reported mitochondrial activity in both amphibian and leech (vector) forms of *Trypanosoma mega* as obtained in culture, though differences in mitochondrial morphology were evident between these stages.

After brief fixation (5 min at 4°C) in 0.1 M cacodylate-buffered 5 per cent glutaraldehyde (pH 7.2), I have examined the distribution of NAD diaphorase activity in several African trypanosomes and found that it agrees with the picture of the chondriome obtained from electron-microscope investigations. In bloodstream *Trypanosoma vivax* and *T. congolense* (which are not polymorphic) the single anterior mitochondrion, kinetoplast and short posterior mitochondrion are filled with blue-black formazan deposit when fixed smears are incubated for 40 min with NADH₂ as substrate and nitro-blue tetrazolium salt as acceptor^{36,37}, indicating diaphorase activity. Stages in division of the chondriome can be seen in such smears. The anterior mitochondrion appears to cleave first in the region of the nucleus, the slit extending backward to the kinetoplast and posterior mitochondrion, and forward to the extremity of the anterior mitochondrion. All the trypanosomes in a smear appear to show diaphorase activity, whereas controls incubated without substrate do not. Electron micrographs of both these bloodstream trypanosomes show well-developed cristae in the chondriome^{17,38}, and there is evidence³⁹ that pyruvate is catabolized, so that, unlike *T. brucei*, the chondriome of *T. vivax* and *T. congolense* appears to be active in the bloodstream phase.

When smears of *Trypanosoma brucei* and allied trypanosomes were tested for NAD diaphorase activity, surprising results were obtained. Old monomorphic laboratory strains showed no diaphorase activity in the mitochondria and similar results were obtained for *T. evansi*. In recently isolated polymorphic strains, however, intense enzyme activity was evident in the chondriome of intermediate and stumpy forms (Fig. 3), while slender forms resembled monomorphic forms in having virtually no diaphorase activity in the mitochondrion. It appears, therefore, that the transition from slender to stumpy forms is accompanied by the acquisition of mitochondrial activity as shown by the intramitochondrial oxidation of NADH₂ (Fig. 4). Controls incubated without the substrate again indicated no enzyme activity.

In slender and monomorphic *Trypanosoma brucei*, and in *T. evansi*, NADH₂ oxidation, as registered by formazan deposits, was occasionally witnessed in extra-mitochondrial bodies scattered throughout the cytoplasm of the bloodstream forms. These granules probably represent the location of the L- α -glycerophosphate (L- α -GP) oxidase cycle, which, as previously mentioned, mediates terminal respiration in bloodstream forms. L- α -GP dehydrogenase is NAD linked, catalysing the reduction of dihydroxyacetone phosphate to L- α -GP by NADH₂; L- α -GP oxidase transfers hydrogen directly from L- α -GP to atmospheric oxygen, yielding dihydroxyacetone phosphate once more.

Further evidence for activity of the chondriome in polymorphic infections comes from the ability of some of these trypanosomes to utilize Krebs cycle intermediates, particularly α -ketoglutaric acid (α -KGA) as shown by a simple motility test⁴⁰. Ryley³⁰ noted that cultured midgut

forms of *Trypanosoma rhodesiense* could maintain their motility if supplied with α -KGA while monomorphic bloodstream forms could not. In the work recorded here, it was found that, when bloodstream forms are washed free of exogenous respirable substrate and suspended in buffered Ringer's solution alone and with added M/10 glucose or M/10 α -KGA, motility is retained in the glucose and α -KGA long after it has ceased in the saline control (Fig. 5). Both slender and stumpy forms are active in the glucose, but in α -KGA only late intermediate and stumpy forms are active.

Morphologically, the respiratory switch is characterized by more than just a change in outward form. In many of the intermediate forms stained for NAD diaphorase activity, the mitochondrion appears to be in a state of division (Fig. 3). Steinert³⁹ has noted in *Trypanosoma mega* that transformation and division appear to be mutually exclusive. Of the different bloodstream forms, only slender trypanosomes are known to divide; it is possible that forms with incipient mitochondrial fission are most sensitive to the transforming stimulus. A further change noted in the transformation from slender to stumpy forms is the increase in diameter of the mitochondrial tube and the appearance of well-defined cristae within its lumen as seen with the electron microscope.

Fig. 3. Distribution of NAD diaphorase activity in late intermediate forms of *Trypanosoma brucei*. Blue-black formazan deposits indicate localization of enzyme in the mitochondrion. The mitochondrion is splitting in the trypanosome on the right.

Fig. 4. NADH₂ oxidation by different stages in the life-cycle of *Trypanosoma brucei*. Sites of substrate oxidation are shown in black (representing formazan deposits derived from reduction of nitro-blue tetrazolium). When slender forms change into intermediate forms the mitochondrion becomes active in NADH₂ oxidation. When stumpy forms enter the fly, proliferation of the active mitochondrion occurs. Salivary gland stages are not shown.

Fig. 5. Graphs to show motility of *Trypanosoma brucei* (*T. rhodesiense*) in Ringer's saline, M/10 glucose and M/10 α -ketoglutaric acid. All forms can utilize glucose to maintain motility. A fraction can also utilize α -KGA indicating mitochondrial activity. This fraction corresponds to the intermediate and stumpy forms.

The nature of the stimulus which causes the transformation bringing about polymorphism and activating the mitochondrion is not known. The most likely instigator of the respiratory switch is a change in permeability of the trypanosome surface. For example, if surface permeability changed to decreased ability to take up glucose, continuation of life would be favoured by a more efficient utilization of what glucose was taken in. Host antibodies might well produce such a surface change. The shortening of body-length might be effected by a contraction of the pellicular microtubules accompanying surface change.

The assumption of mitochondrial activity by the intermediate and stumpy forms may explain why these forms survive in the fly more readily than slender trypanosomes—they are pre-adapted to the mode of respiration necessary in the midgut of the vector. The possibility that the switch might occur when slender forms enter the fly midgut cannot be precluded, however, for Wijers and Willett¹¹ noted transformation of slender forms to stumpy forms in the midgut of *Glossina*.

Hollingshead *et al.*⁴⁰ have noted that monomorphic bloodstream and fly midgut (culture) forms of *Trypanosoma rhodesiense* differ in their electrophoretic behaviour. It would be interesting to see if the change in surface character accompanies the slender-stumpy transformation or whether it takes place on entering the fly midgut or culture medium.

Mitochondrial activity: the genetic basis. The kinetoplast of flagellates has long been known to be a self-replicating structure (see Mühlipfordt⁴¹ for a comprehensive review of its history). The more recent finding that it represents the DNA component of the trypanosome chondriome has brought us nearer to an understanding of its function. Steinert²⁰ regarded the kinetoplast as a genetic system transmitting the information necessary for the synthesis of mitochondrial enzymes. Some evidence for this is forthcoming from a study of trypanosomes which have lost the kinetoplast⁴².

Monomorphic *Trypanosoma brucei*, *T. evansi* and forms closely related to them can spontaneously lose the kinetoplast as a result of faulty division and survive in the bloodstream as akinetoplastic strains⁴³. The akinetoplastic condition can be induced in most trypanosomatids by treatment with certain dyes (for example, acriflavine, pararosaniline)⁴⁴, but the resulting akinetoplastic individuals are only viable in the case of bloodstream *T. brucei* and *T. evansi*, that is, those forms which do not need mitochondrial respiration in the bloodstream. The akinetoplastic trypanosomes appear to be incapable of synthesizing mitochondrial enzymes: in the work recorded here, NAD diaphorase could not be detected in akinetoplastic forms. Reichenow⁴⁵ noted the inability of akinetoplastic *T. gambiense* to infect *Glossina*. The electron microscope reveals, however, that akinetoplastic trypano-

somes retain a membranous ghost of a mitochondrion ('pro-mitochondrion'), and this is found in all their progeny^{42,46}. The kinetoplast may be essential for the synthesis of mitochondrial enzymes; but it is not necessary for the continuous replication of the mitochondrial membrane system.

Once lost, the kinetoplast cannot be regenerated, and this fact has enhanced its reputation of autonomy. But, as yet, there is no evidence that any cytoplasmic organelle with genetic continuity is independent of nuclear control. In the case of chloroplasts and the mitochondria of yeasts, there is ample evidence that the function of these structures is subject to the nuclear genes²⁴. Reports that fusion of the kinetoplast envelope with the nuclear envelope can be observed with the electron microscope^{41,42} have not yet been satisfactorily confirmed; I have never seen such fusion in examining hundreds of sections of juxtannuclear kinetoplasts from different species.

Using yeast as a model, Gibor and Granick²⁴ suggest that mitochondrial DNA represents a multigenic hereditary system. They envisage that, in addition to constitutive genes governing replication, other mitochondrial genes might control the differentiation of enzyme systems through operon-regulator mechanisms⁴⁷ subject to external inducers as well as nuclear influences. In anaerobically grown yeast, oxygen appears to act as an inducer to the synthesis of components of the mitochondrial respiratory system, the cytochrome chain and Krebs cycle enzymes being formed simultaneously⁴⁸. Similar co-ordinate synthesis of respiratory enzymes can be induced by oxygen in an anaerobic plague bacillus, *Pasteurella pestis*⁴⁹. In *Trypanosoma brucei* co-ordinate synthesis of mitochondrial components appears to occur in the transition from slender to intermediate bloodstream forms, but here it is unlikely that oxygen is the inducer; the respiratory switch is not from anaerobic to aerobic respiration, but from aerobic glycolysis to complete oxidation.

The reverse respiratory switch in *Trypanosoma brucei* (that is, back to mitochondrial inactivity) probably takes place in the salivary glands of the tsetse fly, possibly during the genesis of metacyclic forms, but it could equally well occur on entering the bloodstream. The agents inducing regression of mitochondrial activity are not known.

Loss of polymorphism: evolutionary aspects. When a polymorphic strain of *Trypanosoma brucei* becomes monomorphic and non-transmissible, it presumably loses the ability to produce certain mitochondrial enzymes, for it can no longer perform the respiratory switch. The absence of selection for the respiratory switch over several generations in the mammalian bloodstream (possibly provided by rapid passage through laboratory animals) would allow the accumulation of mutations affecting the mitochondrial enzyme systems: a high rate of spontaneous mutation appears to be characteristic of cytoplasmic genetic systems²⁴. A deeper analysis of the mechanisms involved in the evolution of monomorphism is scarcely possible in our present state of uncertainty about the relationship of the host's immune response to polymorphism. If we accept that, in untreated animals, antibodies produced by the host elicit both antigenic change and transformation from slender to stumpy forms in the trypanosomes⁵¹, then we are faced with the question of whether parallel effects are registered in all flagellates or in different fractions of the parasite population. At least two possibilities present themselves.

The simplest possibility is that, under the influence of antibodies, slender forms switch their respiratory pathway and become stumpy; the antigenic change then occurs and the stumpy forms revert to slender forms, as suggested by Wijers⁸; antigenic change is closely linked with polymorphism. But this pattern of behaviour is not in keeping with the observation that syringe-passaged monomorphic strains can change their antigens without changing into stumpy forms⁵². If antigenic change is

linked to polymorphism it is difficult to see why selection maintaining antigenic change has not also maintained polymorphism in old laboratory strains.

The elimination of polymorphism is perhaps more readily explained if antigenic change and transformation are unlinked and regarded as alternative responses on the part of the trypanosome population. Under the influence of antibodies certain slender trypanosomes might switch their respiration and transform into stumpy forms while others might change their antigens and so produce the next variant. As both transformation and antigenic variation can occur within a clone strain, the difference in response must depend on differences in competence (in the embryological sense) rather than genetical heterogeneity within the population. If antigenic change is not bound to transformation, as in this model, then it is conceivable that the ability to transform might be lost in the absence of selection, whereas the ability to undergo antigenic change might be retained, as it is in monomorphic strains. This being so, the slender forms would serve to continue the infection in the mammalian host, the stumpy forms serve to infect the tsetse fly vector. Should the stumpy forms not be ingested by a fly they are eliminated by the host.

I thank Dr. J. F. Ryley for his advice, Mr. T. M. Leach for facilities at the Nigerian Institute for Trypanosomiasis Research, and the Royal Society, the Medical Research Council and the Wellcome Trust for grants supporting this work.

ANCESTRY OF SEA-STARS

IN a recent series of articles, Prof. H. B. Fell¹⁻³ attempted to link the morphology of the skeletal elements of living sea-stars with somasteroids. This early Palaeozoic echinoderm group, originally described from the Ordovician of Europe⁴, is generally held to be ancestral to the asteroids and ophiuroids of to-day. Prof. Fell's researches on living sea-stars have permitted recognition of the close comparison between the skeleton of living forms, in particular the genus *Platasterias*, and archaic somasteroids. Indeed, he refers this genus to the Somasteroidea.

This comparison of living sea-stars with the somasteroids will not be discussed here. It is a broader conclusion which invites the present comment. Prof. Fell³ argues persuasively that somasteroids evolved from the pelmatozoan class Crinoidea, and that they are phylogenetically intermediate between later sea-stars and crinoids. Because other eleutherozoans have a shape different from sea-stars ('meridional growth gradients' in contrast to 'radial growth gradients'), seemingly these echinoderms did not evolve from crinoids. Prof. Fell therefore rejects the sub-phylum Eleutherozoa as polyphyletic, and advocates Haeckel's groupings Asterozoa and Echinozoa.

Two features are taken as indicating the kinship of somasteroids and crinoids. The first is a similarity of the apical plates of many living sea-stars and the pentacrinoid calyx. The second is an apparent relationship of ossicles of a pinnulate biserial crinoid arm and of a somasteroid ray. These are discussed in turn.

(A) *The homology of the apical system of sea-stars and the crinoid calyx.* Living sea-stars, particularly ophiuroids, possess regular circlets of plates around a central adapical ossicle in their early development. These can persist to maturity so that ophiuroids may show a well-defined apical system during all growth stages (Fig. 1c). A similar situation may obtain in living asteroids, although the pattern is more often lost during growth, and radial elements may be absent (Fig. 1d). The pentacrinoid stage of development of living comatulids is very similar. There is a central plate (the dorso-central) surrounded by a circlet of five basal plates (interradial in position) and succeeded by a circlet of five radials (Fig. 1e). During development the basals are lost, as are small infrabasals present in some comatulids.

The various circlets of plates of these apical systems are directly homologized by Prof. Fell³. Now this idea is far from new. It is a partial revival of the so-called 'calycinal theory', which held sway in the latter part of the nineteenth century. As Fell neglects to discuss the facts which led to a rejection of this theory, it is pertinent to trace briefly its rise and fall.

Löwen⁵ appears to have first propounded the theory in detail. He stated that the suranal plate (the central plate of the apical system of calycinal echinoids) was homologous with the centrale of the Cretaceous crinoid *Marsupites* (Fig. 1a, b) and, further, that the echinoid apical system was the homologue of the pentacrinoid calyx.

Similar homologies were suggested for sea-stars. The idea became widely accepted⁸⁻⁹. Main discussion centred on details of homologies between major echinoderm groups. An attempt was made to homologize the circumoral ring of holothurians with oral plates of crinoids⁸; Studer even suggested that echinoid and asteroid apical systems corresponded with monocyclic crinoids, and ophiuroids with dicyclic crinoids⁶. There was general agreement on the homology of the apical systems in living echinoderms, and the consequent view of their close phyletic relationship.

The theory, however, slowly fell from favour. First Neumayr¹⁰ rejected homologies relating to echinoids, for the suranal plate is demonstrably a recent evolutionary development. Sasarin and Sasarin¹¹ also rejected the theory for this reason and, as Mortensen¹² expresses it, "therewith the whole Crinoid phantom". Stürtz¹³, from a study of Palaeozoic ophiuroids, maintained that the theory had no bearing on the ancestry of this group, for he considered that no Palaeozoic ophiuroid shows an apical system. This was later reaffirmed by Spencer¹⁴, and extended in a more general way to Asteroidea. Because it was clear by the turn of the century that the calycinal systems of different echinoderm groups were independent developments late in their evolution, the theory was no longer seriously entertained¹⁵, and, in the ensuing sixty-five years, no new facts have been adduced which call for its revival. In relation to Fell's present views on homologies the fossil record shows that: (1) The patina of living crinoids is highly modified compared with Palaeozoic forbears of the group. The centrodorsal of comatuloids, and the absence of an anal plate associated with the right posterior radial are post-Palaeozoic developments. (2) No pre-Carboniferous ophiuroid shows an apical system comparable with that of living ophiuroids. (3) Lower Palaeozoic asteroids such as *Hudsonaster* may show regular series of apical plates, but these defy close comparison with the later calycinal systems, and are fundamentally different from those of contemporary crinoids.

(B) *The homology of the crinoid arm and the somasteroid ray.* The comparison between the ossicles of the arm of a living biserial crinoid and those of a somasteroid ray is striking (Fig. 2). In the former the brachials support the pinnules; in the latter the ambulacral ossicles support the virgalia. These are directly homologized by Prof. Fell⁸.

Fig. 1. Calycinal systems of various echinoderms. Plates homologized by Prof. Fell similarly labelled (C="centrodorsal"; B="basal"; R="radial"). a, Apical system of calycineid stirodont echinoid; b, ventral view of the calyx of the Cretaceous articulate crinoid *Marsupites*; c, adapical view of the disk of an immature specimen of the living ophiuroid *Ophiosteira*; d, adapical view of a juvenile specimen of the living asteroid *Ophiopyrgus*; e, ventral view of the calyx of the pentacrinite stage of development of the living articulate crinoid *Promachocrinus*; f, anterior view of a typical Ordovician camerate crinoid *Archaeocrinus*. Note uniserial brachia rigidly incorporated in the polyplacate theca; inter-radials stippled. (a-b after Lovén (ref. 5); c-e after Fell (ref. 3))

Fig. 2. Supposed morphological transition from a uniserial pinnulate crinoid arm through to the ray of a living sea-star *Platasterias*. a, Uniserial crinoid arm; b, biserial crinoid arm; c, chelonicasteroid somasteroid ray; d, *Platasterias* ray. (Modified from Fell (ref. 3))

Now, are these truly homologous structures? If *Platasterias* can be considered a somasteroid, and if we are entitled to compare it with a living crinoid, then differences are sufficient to suggest that the arrangements are only analogous. Pinnules of crinoids are arms in miniature; they bear food grooves and branches of the water vascular system; in *Platasterias* the food grooves are located between the virgalia and particles are passed to the radial groove by ciliary action². In sea-stars the aboral body-wall and perivisceral coelom extend into the rays; this is not so in crinoids.

No solution to the question of homology (or, indeed, to the whole question of sea-star ancestry) can be found without reference to the fossil record. It is possible, in terms of the evolution of Palaeozoic crinoids, for a crinoid with biserial pinnulate arms to have given rise to somasteroids.

Somasteroids appear in the Tremadocian (earliest Ordovician). The oldest described crinoid is apparently *Iocrinus cambriensis* (Hicks) of Lower Arenigian (upper Lower Ordovician age)¹⁶. This inadunate crinoid, in accordance with primitive members of the sub-class, possesses uniserial, non-pinnulate arms. Through a process of heterotomous branching, pinnules were developed by inadunates in the Silurian, but it was not until the Carboniferous that biserial pinnulate arms evolved. This group could not have given rise to somasteroids in the late Cambrian.

The Flexibilia must also be discounted as a possible ancestral group for simple, non-pinnulate arms are retained throughout its entire history. Therefore, if the somasteroid ray evolved from a crinoid arm it must have evolved from a camerate crinoid. Camerate crinoids appear first in Middle Ordovician times and, although all camerates have pinnules, early representatives possess uniserial arms. The distal ends of rami may become biserial in Upper Ordovician forms, but it is not until Middle Silurian times that biserial pinnulate arms are common. The evolution of the camerate arm therefore parallels that of the Inadunata.

Now camerate crinoids are very different from other crinoids. Early representatives possess a polyplacate theca in which the proximal brachials are incorporated (Fig. 1f). The posterior is modified by anal plates different from those of other crinoids both in origin and modification. A rigid tegmen covers the mouth and food grooves which therefore pass into the theca at the bases of the free brachia. The first camerates therefore contrast strongly with the contemporary pauciplacate Inadunata. Indeed, Jaekel^{17,18} separated the Camerata as his Cladoidea, considering that they arose independently from polyplacate cystoids. That camerates are phylogenetically distinct from other crinoids cannot be doubted.

For the camerate arm to produce a somasteroid ray, a biserial condition must have existed in the most proximal brachials to give the mouth frame (Fig. 2). Because of the inclusion of fixed 'brachials' in the cup, it can be asserted that this condition does not obtain in any camerate crinoid. Even in later Palaeozoic camerates in which brachials may become free above the radials, the proximal brachials remain uniserial.

It is therefore concluded that:

(1) The seeming homology of the apical systems of living sea-stars and crinoids, and the suggested homology of the pinnulate biserial crinoid arm and the somasteroid ray are plausible only if living forms are studied. If Palaeozoic echinoderms are considered neither interpretation can be sustained.

(2) The similarity of the apical systems of living sea-stars and crinoids is due to convergence, and no strict homology of the plates represented therein is possible. Arrangements of plates seen in living representatives of each group are demonstrably recent evolutionary developments and have no bearing on phyletic relationships.

(3) Present understanding of the evolution of Palaeozoic crinoids prohibits the conclusion that somasteroids hold a phyletic position intermediate between crinoids and later sea-stars. Not only do somasteroids appear before crinoids in the fossil record, but early crinoids show a progressive evolution of the arm structure toward biserial pinnulate arms (necessary in a crinoid ancestor of the Somasteroidea) which were developed by the Carboniferous in the Inadunata, and by late Ordovician times in the Camerata (if they be properly regarded as crinoids). No camerate crinoid, however, shows biserial brachials immediately above the radials, a condition demanded by the hypothesis of the homology of the crinoid arm and the somasteroid ray. The supposed evolution of somasteroids from crinoids is opposed to the evidence of the fossil record, as is any other hypothesis involving their close phyletic relationship.

What positive conclusion can be reached as to the origin of sea-stars and their relationship to other echinoderm classes? The older view that asteroids were derived from edrioasteroids was based on the inferred homology of the plates of an open ambulacral groove in these classes. Spencer's work on somasteroids⁴, the first of the sea-stars, led him to reject this hypothesis. At present no worthwhile alternative can be offered. Indeed, as our knowledge of early Palaeozoic echinoderms increases so any apparent relationship of the various eleutherozoan classes diminishes (except, perhaps, the echinoids and holothurians). The mutual relations of the free echinoderm groups are as obscure one to another as they are to the Pelmatozoa.

THE gist of Dr. G. M. Philip's article is that, in advocating the homology of the asterozoan and crinozoan calyx, I have neglected the historical development of the calycinal theory; have inferred the homology of the echinoid apical system with the calyx of crinoids in spite of the fact that such homology was disproved long ago by authors he cites; have similarly included the calcareous ring of holothurians in the inferred homology; have failed to account for the absence of a calyx from pre-Carboniferous ophiuroids, and from the Palaeozoic Hudsonasteridae; have failed to indicate the serious difficulty of deriving a somasteroid

from a crinozoan when no suitable crinoid is yet known from pre-Ordovician horizons; and have in general paid insufficient attention to fossils, the conclusions reached being plausible only when considered in the context of recent forms.

I fear that Dr. Philip has not had access to all the literature included in his reference list, for he has unfortunately misconceived my views.

The inference that "there is no real calyx at all in echinoids and holothurians", which is what Dr. Philip appears to be saying, is expressed in precisely those words in one of the papers he cites (ref. 1, p. 421); I cannot imagine why he omits my name from his list of authors who reached this view.

His inclusion of the holothurian calcareous ring in his discussion of the inadequacies of the calycinal theory seems pointless, since I have never advocated such a hypothesis as to its homology. He appears to be unaware of the recent publications in which the homology of this structure with the ambulacral oral skeleton of edrioasteroids is deduced², and its relationship to the subsequent evolutionary trends of holothurians utilized in a taxonomic context⁴.

In taxing me with failure to account for the absence of a calyx from pre-Carboniferous ophiuroids, he ignores my lengthy discussion of this topic (ref. 1, pp. 416-421), where the conclusion is reached that "the late Palaeozoic Aganasteridae . . . have been wrongly interpreted as giving evidence of the late appearance of the calyx in phylogeny in ophiuroids"; and in particular he omits all reference to the published finding that calyx plates are transitory features in the embryonic stages in surviving members of archaic ophiuroid groups, the succeeding adult stages having a naked disk, and the consequential inference that this fact "gives the explanation of why we do not find a calyx in Palaeozoic fossil ophiuroids" (ref. 1, p. 420). Similarly, Dr. Philip's remarks on *Hudsonaster* imply that he is producing this criticism *de novo*, completely omitting to state that the Hudsonasteridae have been found to fall in a late (that is, post-astropectinid) grade of asteroid morphological differentiation (ref. 1, pp. 389, 391). He likewise ignores my published conclusion (ref. 1, p. 392) that "The fossil Hudsonasteridae . . . are too specialised to have much relevance to the origin of asteroids".

The differences between somasteroids and crinoids listed by Dr. Philip are offered without any acknowledgment that these same differences, expressed in much greater detail, have already been set out in the literature (ref. 1, pp. 411-422), and that a hypothesis was also deduced to account for the differences.

Dr. Philip especially stresses the fact that no crinoid with suitable structural features is provided by the fossil record at a sufficiently low horizon for it to be considered ancestral to somasteroids. I was, in fact, the first to stress this very difficulty (ref. 1, pp. 423-424); neither does he mention my plea that final judgment be withheld pending further investigation of Cambrian sediments, especially in the Indo-Pacific, nor does he indicate the cases to which I directed attention where subsequent finds have demonstrated the dangers of relying on the known geological time-ranges of groups in the face of morphological evidence to the contrary. The repeated recognition of so-called 'living fossils' demonstrates how incomplete the geological record is at present.

Dr. Philip's claim that the suggested homologies are plausible only if living forms are considered is surely refuted by the mass of data, including much new data, on fossils included in the papers he cites. Except for new specimens not yet reported on, my paper was based on an examination of all known specimens of fossil somasteroid, not to mention many other fossils; and before publishing my conclusions I circulated them, and the data on which they rest, among palaeontologists in Europe and America known to be interested in the topic, and their valuable

opinions were individually acknowledged (ref. 1, p. 434); surely it cannot be said that relevant fossil evidence was ignored.

Questions relating to the phylogeny of echinoderms, the homologies of the calcareous ring, the calyx and the apical system of echinoids, and the origin and affinities of the asterozoans, are of broad interest to both zoologist and palaeontologist. They have prompted much international co-operation and co-ordination of research and publication over the past few years, as witness contributions now on point of issue from the Press⁴⁻⁷. In addition, work is now actively in progress on Palaeozoic asterozoans and echinozoans at this University and, far from ignoring palaeontological evidence, our aim is to co-ordinate it with that yielded by the morphology of extant forms.

Finally, I must protest at the incorrect use of diagrams taken from my paper¹ in Dr. Philip's Fig. 1, which he captions "Calyceinal systems of various echinoderms".

The juxtaposition of echinoid apical systems with crinoid and asterozoan calyces serves only to discount the alleged homology of all these structures, a homology which I have never supported, and have in fact opposed, as stated here.

NATURE OF THE NON-HAEM IRON IN FERREDOXIN AND RUBREDOXIN

By DR R. D. GILLARD, DR. E. D. MCKENZIE, PROF. R. MASON, S. G. MAYHEW*,
DR. J. L. PEEL* and J. E. STANGROOM

Department of Chemistry and Agricultural Research Council Unit for Microbiology, Department of Microbiology, University of Sheffield Id

THE name 'ferredoxin' was first introduced by Mortenson, Valentine and Carnahan¹ for a brown, non-haem, iron-containing protein of low redox potential which they isolated from *Clostridium pasteurianum* and which was shown to function as an electron carrier in that organism. Closely similar proteins have since been isolated from several other anaerobic bacteria.

Tagawa and Arnon² showed that this bacterial ferredoxin has several properties in common with a brown iron protein from plants (previously identified as haemoglobin-reducing factor³ and "photosynthetic pyridine nucleotide reductase"⁴) although there are marked differences in their electronic absorption spectra. They extended the use of the term 'ferredoxin' to include this plant substance. A brown pigment recently isolated from the photosynthetic bacterium *Rhodospseudomonas palustris* has an absorption spectrum close to that of plant ferredoxin⁵.

A red protein, observed to separate during the purification of ferredoxin from *C. pasteurianum*^{6,7}, has recently been crystallized by Lovenberg and Sobel⁸ and shown to contain non-haem iron. It was found to act as an electron carrier, but the absorption spectrum was different from those of bacterial and plant ferredoxins. The name 'rubredoxin' was proposed. A protein which is identical in all properties so far examined has been isolated from *Peptostreptococcus elsdenii* by one of us (S. G. M.), while Wilder, Valentine and Akagi⁹ prepared a protein with a similar absorption spectrum and electron carrier function from *Clostridium thermosaccharolyticum*. These last-mentioned authors described their product as a 'ferredoxin'.

In accordance with the predominant present practice, we shall, for convenience, refer to these three types of protein as 'bacterial ferredoxin', 'plant ferredoxin' and 'rubredoxin', respectively. This nomenclature is, however, recognized as having certain shortcomings.

We now report the results of optical rotatory dispersion and other work on bacterial ferredoxin and a rubredoxin, which allow us to make some general comments on the nature of the non-haem iron atoms in these proteins.

The ferredoxins from *C. pasteurianum* and *P. elsdenii* were prepared, with minor modifications, by the method of Mortenson⁷ from cell material provided by the Microbiological Research Establishment, Porton.

Rubredoxin was prepared from *P. elsdenii* by first following the procedure for ferredoxin and then eluting the rubredoxin from diethylaminoethylcellulose (DEAE) with 0.4 M *tris*-HCl buffer of pH 8.0. Further purification was by chromatography on two successive columns of DEAE developed with 0.15 M *tris*-HCl buffer of pH 7.6, containing sodium chloride (0.2 M). Ferredoxin from *C. acidi-urici* was given to us by J. C. Rabinowitz, and the plant ferredoxin, prepared from parsley, was a gift from H. E. Davenport. All measurements used aqueous solutions of the proteins in 0.05 M *tris*-HCl buffer of pH 7.3-7.4.

The electronic spectra. The rotatory dispersion spectra of the bacterial ferredoxins from *C. acidi-urici*, *C. pasteurianum*, and *P. elsdenii* are all extremely similar in the visible and near ultra-violet regions (Fig. 1). The absorption spectra of these ferredoxins show a band centred at 390 mμ with a long structureless tail extending into the visible region where no distinct absorption bands can be discerned⁶, but the optical rotatory dispersion data indicate the presence of two optically active transitions centred at 490 mμ and 570 mμ, underlying this diffuse absorption tail. The signs of the Cotton effects of these bands are negative (490 mμ) and positive (570 mμ), respectively, in all three ferredoxins. Attempts to measure the circular dichroism of these bands have been unsuccessful as yet because of the high optical densities of the protein solutions. The rotatory dispersion spectrum of rubredoxin from *P. elsdenii* is very similar to that of the bacterial ferredoxins; the electronic absorption spectrum of rubredoxin actually shows resolution of the absorption bands at 490 mμ and 570 mμ, the presence of which in the bacterial ferredoxin could only be deduced from their dispersion curves. The Cotton effects are again negative (490 mμ) and positive (570 mμ) (Fig. 2). The optical rotatory dispersion spectrum of parsley ferredoxin is shown in Fig. 3; it is closely related to that reported by Ulmer and Vallee¹⁰ for spinach ferredoxin but different from that of the bacterial ferredoxins and rubredoxin.

These results suggest:

(1) That the chromophores responsible for the visible and near ultra-violet absorption spectra of rubredoxin and bacterial ferredoxin are in similar asymmetric environments.

(2) That the bonding of the iron in plant ferredoxin is entirely different from that in bacterial ferredoxin and

* Present address: Earlham Food Research Laboratory, Recreation Road, Norwich.

rubredoxin. If the nature of the iron atom be regarded as critical in deciding the scope of the term 'ferredoxin', it should clearly include rubredoxin but exclude plant ferredoxin.

(3) That, since the absorption and rotatory dispersion data for the bacterial ferredoxin and rubredoxin are unrelated to those which have been previously reported for other non-haem iron proteins (for example, ref. 10), the nature of the metal-ligand bonds in the bacterial ferredoxin and rubredoxin systems is so far unique.

A quantitative consideration of the Cotton effects in bacterial ferredoxin and rubredoxin provides further useful information. The relative magnitudes of the Cotton effects allow the characterization of the various electronic transitions. The most strongly optically active bands in the spectrum are centred at 570 m μ and 490–500 m μ , which suggests that they are magnetic-dipole-allowed transitions of the ligand-field type; the absorption band at 390 m μ shows a much weaker Cotton effect, and may well arise from a charge-transfer type of transition, presumably involving the iron and the sulphur ligands. The amplitude of the Cotton effect from the trough at 530 m μ to the peak at 470 m μ for a given concentration of

material provides a quantitative physical characteristic which may be useful in characterizing and assaying bacterial ferredoxins and rubredoxin.

Reduction of ferredoxin and rubredoxin. Support for the assignment of the transitions at 565, 490 and 390 m μ to iron-sulphur chromophores is provided by observations on the behaviour of both rubredoxin and bacterial ferredoxins on reduction. Reduction by dithionite ions leads to the loss of the absorption bands and of the Cotton effects in the visible and near ultra-violet region. A new Cotton effect appears at 320 m μ . Identical changes were observed when the reduction was carried out enzymatically, using hydrogen with a small amount of a ferredoxin-free preparation from *P. elsdentii* as a source of hydrogenase. Illustrative data are given in Fig. 4. On shaking the reduced preparations in air, the optical rotatory dispersion spectra of the original oxidized species were regenerated. These observations indicate that the changes in the chromophores resulting from chemical and enzymatic reduction are identical and are the same for all three bacterial ferredoxins and rubredoxin. They also add strong support to previous evidence that the iron atoms in these proteins are intimately involved in their enzymatic activity.

The optical rotatory dispersion spectrum of the oxidized ferredoxin from *C. acidi-urici* is unchanged following the addition of the metal-chelating agents, α, α' -bipyridyl and o-phenanthroline, no characteristic absorption at approximately 520 m μ of the trischelateferrous complexes appearing within 30 min. It is therefore clear that the iron is non-labile. On reduction, however, with dithionite ions, in the presence of α, α' -bipyridyl, the rotatory dispersion spectrum, in the visible region, of ferredoxin disappears and is replaced by that of reduced ferredoxin. These changes are accompanied by the appearance, within a few minutes, of the characteristic visible absorption band of the tris α, α' -bipyridyliron(II) cation. It seems clear that reduction of the protein renders the iron labile, it being then accessible for bipyridyl substitution. It is noteworthy that apoferredoxin may be prepared from reduced ferredoxin by complexing the iron as a tris (α, α' -bipyridyl)iron(II) salt, which is later removed by dialysis, and that on treatment of the apoferredoxin with ferrous iron, ferredoxin is reconstituted¹². We find, from dialysis experiments with the ferredoxin of *C. pasteurianum*, in the absence of bipyridyl, that a considerable part of the iron of the reduced ferredoxin may be removed by dialysis; this is not the case for the oxidized ferredoxin, where only a very small loss of iron was observed in dialysis.

The tris (α, α' -bipyridyl)iron(II) cation produced when bacterial ferredoxin or rubredoxin is reduced by dithionite ions in the presence of bipyridyl is optically inactive. In general, the substitution of a transition metal ion in an asymmetric site leads to the production of one enantiomer of any resolvable product in marked excess over the other. The lack of optical activity in the trisbipyridyl iron(II) cation formed from reduced bacterial ferredoxin and rubredoxin implies that the complexable iron in the reduced species is in a site of low asymmetry, and that the highly asymmetric environment of the iron in oxidized ferredoxin, evidenced by its rotatory dispersion spectrum, is changed on reduction.

This alteration in the environment of the iron atom when bacterial ferredoxin is reduced is also clear from the changes in rotatory dispersion which occur. In other redox systems involving asymmetric iron chromophores, if the asymmetry about the iron atom remains unchanged, the Cotton effects of the oxidized and reduced states are of the same order of magnitude. For example, the resolved tris α, α' -bipyridyl iron(II) cation shows a series of Cotton effects in the visible region; the tris α, α' -bipyridyl iron(III) cation formed from it by oxidation shows different Cotton effects in the visible spectrum. Since only one electron transfer is involved in this oxidation, the helical environments about the iron atoms are the same in the reduced and oxidized states, the asymmetry of the iron chromophores is similar, and the order of magnitude of the Cotton effects is the same for the complexes of iron(II) and iron(III).

Behaviour in urea solutions. The asymmetry in the environment of the iron atoms in oxidized bacterial ferredoxin does not appear to depend on the secondary or tertiary structure of the protein. In the presence of 8 M urea, the absorption spectrum and optical rotatory dispersion in the visible region of oxidized ferredoxin from *C. acidi-urici* are initially no different from those in water (Fig. 1). However, in solutions of urea and α, α' -bipyridyl, the complex tris(α, α' -bipyridyl)iron(II) cation is formed quite readily from oxidized ferredoxin of *C. acidi-urici* and *C. pasteurianum*. The rate of formation of trisbipyridyl complex from *C. acidi-urici* ferredoxin has been followed spectrophotometrically, a first-order law being observed with $k = 2.2 \times 10^{-3}$ sec⁻¹. Clearly, the iron is not completely labilized in the presence of urea, since if it were, the formation of the trisbipyridyl complex would be instantaneous. Moreover, the trisbipyridyl iron(II) cation produced by the urea treatment is the optically active (-) [Fe(bipy)₃]²⁺, which must be produced through

a stereoselective stepwise reaction with the iron in a highly asymmetric site in the oxidized protein. The rotatory dispersion curve of the (-) [Fe(bipy)₃]²⁺ observed in this work is enantiomorphous with that of the less-soluble diastereoisomer (+) [Fe phen₃] (+) antimonyl tartrate.

There is no discontinuity in the rate of formation of the trisbipyridyl complex in the experiments with urea, the electronic spectra and rotatory dispersion measurements showing the disappearance of the original visible absorptions in ferredoxin after approximately 2 h. Thus the iron atoms, which gave the ferredoxins their characteristic chromophore, appear to be removed completely by this treatment. This suggests that either the iron atoms are all in kinetically equivalent sites or that in a polynuclear model¹¹ a slow rate-determining reaction of the bipyridyl with the terminal iron atoms is followed by a fast reaction with the remaining ones.

Blomstrom, Knight, Phillips and Weiher have proposed a model for the active site in ferredoxin, based on magnetic and Mossbauer effect measurements, which involves a linear array of seven iron atoms with bridging sulphur atoms¹¹. One essential feature of this model—the presence of 'inorganic' sulphide in the molecule—has recently been questioned by chemical evidence¹². (We have also found that metal complexes of cysteine and its peptides evolve H₂S on acidification of their solutions and that it is therefore likely that the 'labile inorganic sulphur' reported previously is derived from cysteine residues.) Since the rubredoxin from *C. pasteurianum* probably contains two iron atoms per molecule (mol. wt. ~6,000), and will carry out some of the biological functions of ferredoxin⁸, there is no compelling reason to assume that all seven iron atoms in ferredoxin lie very close to one another. Indeed, X-ray crystallographic data for ferredoxin from *C. acidi-urici* at a resolution of ~3.0 Å appear to rule out such an arrangement¹³. The amino-acid sequence in ferredoxin (*C. pasteurianum*)¹⁴ shows that there are two sets of cysteine residues in groups of four. A possible explanation for our work is that the two sets are brought together by the iron atoms in oxidized ferredoxin and are separated in the reduced molecule. Structure factor amplitudes calculated for a set of four irons in oxidized ferredoxin (*C. acidi-urici*) show a promising agreement with the observed X-ray data.

The present work also emphasizes the difficulty in assigning a formal oxidation state to the iron atom since it is evident that the iron may appear in either valence state in a way which depends critically on experimental conditions. There exist intrasystem reduction and oxidation mechanisms that have yet to be clarified.

We thank the Agricultural Research Council for a maintenance grant (S. G. M.) and the Science Research Council for the award of a fellowship (J. E. S.), for financial support (E. D. McK.), and also acknowledge other research grants. We thank Dr. H. E. Davenport, Dr. J. C. Rabinowitz and the Microbiological Research Establishment for samples of the several ferredoxins and cell materials.

LETTERS TO THE EDITOR

GEOPHYSICS

Antimatter and Tree Rings

RECENTLY, Cowan *et al.*¹ discussed the interesting case of the Tunguska meteor—the event and its origin mainly in the context of release of a rather high energy of $\sim 10^{24}$ ergs on its impact. Various theories concerning its origin and the nature of the energy source were discussed (for example, asteroidal origin and energy from impact or nuclear reactions). They have shown that none of the theories can satisfactorily explain the amount of energy released during the impact. The authors have invoked the antimatter hypothesis and, as an experimental verification to this, have calculated the expected increase in the carbon-14/carbon-12 ratios in the atmosphere subsequent to the fall of the meteorite. Considering the total energy release, they obtained a value of 7 per cent for the expected increase in activity. Their measurements of the atmospheric carbon-14/carbon-12 ratios, based on annual rings of a 300-yr.-old tree, show a possible increase of 1 per cent in the year 1909, leading them to the conclusion that probably 1/7th of the energy release in the Tunguska meteorite impact came from antimatter annihilation.

It is the purpose of this communication to point out that the probability of such an interesting conclusion is unfortunately very much reduced if one considers the nature of secular variations of carbon-14/carbon-12 ratios in the atmosphere. It was Stuiver² who first pointed out that there existed a good inverse correlation, for the past 1,300 yr. of record, between the solar activity and carbon-14/carbon-12 ratios in the atmosphere. (In what manner sunspot activity brings about this correlation is, however, not well understood as yet.) If we compare the solar activity and the observed carbon-14/carbon-12 ratio during 1870–1933, within the errors of measurements, we do find a fair anticorrelation between the sunspot activity

Fig. 1. Measured carbon-14 activity in tree rings (ref 1) and sunspot activity during the same period

and the carbon-14 deviations (see Fig. 1), there being some phase differences which are not unexpected because of time delays in interactions of relevance to the carbon-14/carbon-12 ratios, for example, air-biosphere and air-sea exchange.

Thus, it is clear that if one takes into account the nature of secular variations of carbon-14/carbon-12 ratios in the atmosphere, it becomes difficult to reach any conclusions which may be of significance to a possible antimatter content of the Tunguska meteorite.

PHYSICS

Delayed Fluorescence from Organic Crystals

DELAYED fluorescence lifetimes and spectra have been observed from crystals of naphthalene, anthracene, pyrene, 3,4-benzpyrene, *t*-stilbene and *p*-terphenyl, using conventional techniques¹. In each case a delayed fluorescence spectrum was observed with a resolution of 8 nm, the spectrum being identical with the prompt fluorescence spectrum. Precautions reported necessary for the observation of delayed fluorescence from micro-crystalline samples² were not found important in the present work, as the crystals used were at least 1 mm thick.

A description of phosphorescence and delayed fluorescence in pure and mixed crystals has been obtained, based on a triplet-triplet annihilation process and assuming a uniform distribution of impurity traps throughout the host crystal^{3,4}. This description predicts an extremely rapid triplet-triplet annihilation rate in pure crystals, or crystals containing a high concentration of impurity traps. Associated with such a rapid annihilation rate is a very short lifetime of delayed fluorescence, and, consequently, a vanishingly small efficiency of phosphorescence and delayed fluorescence when observed using normal msec time resolution techniques.

In the present work, the triplet-triplet annihilation rate constant (γ) has been calculated from delayed fluorescence measurements made on commercially available anthracene crystals. For times short compared with the triplet lifetime, the fluorescence signal (F) is given by⁵:

$$F = \frac{1}{2} A \gamma [\eta_{T0} / (1 + \gamma \tau_{T0})]^2$$

where A is an instrumental factor and η_{T0} the initial density of triplet states. From a plot of $1/\sqrt{F}$ against t , the ratio of slope/intercept gives the quantity $\gamma \tau_{T0}$. Linear plots were obtained for each anthracene crystal, the results being similar to work reported previously for anthracene crystals⁶. For excitation times (t_x) short compared with the triplet lifetime, the initial density of triplets is given by:

$$\eta_{T0} \doteq Q_T t_x \varepsilon I_0$$

Q_T represents the efficiency of triplet formation, equal to one minus the prompt fluorescence efficiency⁷. This gives $Q_T = 0.35$ for thick anthracene crystals⁸. ε is the absorption coefficient for the exciting light⁵. I_0 is the exciting light intensity measured using a thermopile.

Table 1

Crystal thickness	Prompt fluorescence decay time	Delayed fluorescence decay time			$\gamma\eta\tau_0$	γ
		(1) 365 nm	(2) 434 nm	(3) 550 nm		
1 mm	23×10^{-9} sec	1.4×10^{-3} sec	1.6×10^{-3} sec	—	$1 \cdot 10^3$	1.7×10^{-11} cm ² /sec
2 mm	23 " "	2.0 " "	1.3 " "	—	0.45 "	0.75 " " "
5 mm	26 " "	5.6 " "	6.6 " "	8.2×10^{-3} sec	0.40 "	0.89 " " "
20 mm	25 " "	5.7 " "	3.9 " "	5.8 " "	1.5 "	2.5 " " "

Table 1 shows values of the exponential decay times for delayed fluorescence from anthracene: (1) for surface excitation of the crystal using light of wave-length 365 nm; (2) for volume excitation using weakly absorbed light of 434-nm wave-length; (3) for excitation directly into the triplet (3L_a) state using light of wave-length longer than 500 nm. Graphically estimated values of $\gamma\eta\tau_0$ and the values thus calculated for γ are also shown. These results were derived from the volume excitation data (column (ii)) for each crystal.

An additional value of γ was obtained using an extremely pure zone refined sample of anthracene 4 mm thick. In this case, the value for γ of $2.1 \cdot 10^{-11}$ cm²/sec was similar to the values obtained from the unpurified samples.

The mean of the values obtained for the triplet-triplet annihilation rate constant (γ) of $1.6 \cdot 10^{-11}$ cm²/sec is in good agreement with previously reported values of from $1.0 \cdot 10^{-11}$ to $5.5 \cdot 10^{-11}$ cm²/sec (ref. 9), but is lower than a minimum value of about 10^{-9} cm²/sec, calculated from recent data on the diffusion coefficient for anthracene crystals¹⁰.

Observations have also been made of the delayed fluorescence from pure and impure samples of anthracene and naphthalene as a function of temperature. The relative intensity of delayed fluorescence (I_D) was measured as a function of the exciting light intensity (I_0) for each crystal sample, I_0 being altered using a series of wire mesh light attenuators.

Commercially available (impure) samples of naphthalene and anthracene at room temperature, showed $I_D \propto I_0^2$ when excited with strongly absorbed light. The same result was obtained with excitation directly into the naphthalene and anthracene triplet levels.

After prolonged zone refining under vacuum, however, pure crystals of anthracene and naphthalene exhibited a linear dependence ($I_D \propto I_0$) of delayed fluorescence with exciting light intensity (Table 2). Excitation of the pure crystals directly into the triplet state showed $I_D \propto I_0^2$ as found using the impure crystals. None of the pure crystals used in these measurements showed any phosphorescence at 77° K.

Table 2

Temperature	Naphthalene Lifetime		Anthracene Lifetime	
293° K	$5.2 \cdot 10^{-3}$ sec	$I_D \propto I_0^{1.0}$	$2.1 \cdot 10^{-3}$ sec	$I_D \propto I_0^{1.0}$
196° K	6.1 " "	$I_D \propto I_0^{1.3}$	3.9 " "	$I_D \propto I_0^{1.2}$
77° K	50 " "	$I_D \propto I_0^{1.4}$	30.2 " "	$I_D \propto I_0^{1.4}$

Both naphthalene and anthracene showed an increase in delayed fluorescence lifetime as the crystal temperature was reduced, and showed a change in the intensity dependence towards the impure crystal behaviour (where $I_D \propto I_0^2$).

Observations of crystals of pyrene, 3,4-benzpyrene, *t*-stilbene and *p*-terphenyl as a function of crystal purity showed behaviour similar to naphthalene and anthracene. The lifetimes of delayed fluorescence increased as the crystal temperature was reduced. Attempts to increase the purity of the samples (by further zone refining) decreased the lifetime of delayed fluorescence in some cases to <0.1 msec, and produced a corresponding decrease in efficiency of emission.

These results show an increase in triplet lifetime and decrease in triplet-triplet annihilation rate associated with either a decrease in temperature or with the addition of impurity to a pure crystal. Nevertheless, a description of

delayed emission from organic crystals in terms of triplet-triplet annihilation alone does not appear to be sufficient, in view of both a linear and square intensity dependence being observed from a singlet and triplet excited pure crystal respectively. A previous report has shown also a linear dependence for delayed excimer fluorescence from pyrene crystal and solid solution¹¹. It seems likely, therefore, that the storing of energy in singlet trapping states may act simultaneously with the process of triplet annihilation, both these processes contributing to delayed emission from the crystal.

We thank Dr. J. B. Birks for his advice. One of us (G. F. M.) also thanks the Science Research Council for the provision of a maintenance grant.

Transmission through a Tapered Quartz Tube in the Laser Near Field

THE concentration of laser light by the use of tapered dielectric tubes and rods has been discussed by Vogel¹. The purpose of this communication is to report the dependence of the transmission on the position of the tube in the laser near field. The laser near field pattern for circular apertures is a function of $a^2/\lambda X$, where a is the aperture radius, λ is the wave-length of the light (6328 Å for the He-Ne laser used in this experiment), and X is the distance from the aperture². In this case the laser beam was expanded, collimated, and passed through apertures with various known values of a . The quartz tube is shown in Fig. 1.

Fig. 2 shows the per cent energy transmission through the tube as a function of $a^2/\lambda X$ for various values of a . As expected, the transmission depended on a . Of more interest for the work recorded here is the fact that the

Fig. 1

Fig. 2

transmission appears to peak somewhere in the range $2.5 < a^2/\lambda X < 3.0$. Similar behaviour has been noted for focusing with a mirror in the near field². The transmission percentage could be increased by better choice of α , optimum taper design, appropriate optical coating, etc. It appears to be true, however, that the percentage transmission for a given tube depends on its position in the laser near field.

Surface Charges on Arc Track Oxide Layers

In experiments by us and by others¹, with arcs driven by magnetic fields along non-refractory metal electrodes, it has been found that the arc velocity increases when the arc travels over the electrode surfaces a second and subsequent times, within a short time interval after the first run. Other experiments with a short arc rotating around annular electrodes² have shown that, above a certain gas pressure, the forward velocity was no longer limited by the time taken for the transfer of emitting sites along the cathode surface, as occurred with a single passage of the arc. In each case the time needed to set up new emitting sites has apparently been considerably reduced by the previous passage of the arc. If cold-cathode arc emission is due to the charging of oxide layers by positive ions³, then a possible cause of these results would be that some positive ions remain un-neutralized on cathode oxide layers for appreciable times.

In order to investigate this possibility, cathode and anode tracks on various non-refractory metals have been examined by electrometer methods. Two methods were used in order to check whether their results were in agreement, as in fact they have proved to be. In the first,

the arc track to be examined was formed on a rotating disk by arcing to a radial electrode, and driving the arc outwards across the disk and electrode by a magnetic field. The arc track thus formed passed periodically under a probe connected to the grid of an electrometer pentode, and the voltage across the valve was displayed on a cathode-ray oscilloscope. By this method it was possible to measure pulses occurring at each passage of the track under the probe within 8 msec of its formation, and then at any time thereafter. The Kelvin vibrating electrode method with the same electrometer and probe, and a thin strip electrode, was used to confirm the results.

It has been found that on both cathode and anode tracks of all metals tested (aluminium, copper, brass and platinum) the polarity of the pulses has been that corresponding to negative charges on the tracks. After a rapid initial decay, the pulse height decreased relatively slowly and after 6 weeks was still about 25 per cent of the initial value. The p.d. between that of the arc track and that of the surrounding metal surface was mainly in the range 0.1–0.5 V within a few msec of the passage of the arc, and was generally somewhat lower on the anode than on the cathode, an exception being a high-current high-velocity arc on brass where the reverse was found.

The pulses in the rotating disk method could arise from: (1) variation of capacitance between the probe tip and disk; (2) collection at the probe of electrons emitted from the track; (3) differences between the distribution of charge or the oxide thickness on the track and that on the surrounding surface. The first possibility may be eliminated since surface measurements showed a small depression in the region of the arc track, which would tend to give rise to an extremely small positive pulse.

Although there is the possibility of significant electron emission within a very short time of the establishment of the tracks, for various reasons it appears to be more likely that the voltages measured are differences in surface p.d. between the track and the rest of the surface, due to dipole layers on the oxide caused by adsorbed gas. They could arise because the oxide layer is thicker on the track than on the rest of the surface with both having the same negative-charge density, or because the oxide thicknesses are the same but the track offers more adsorption sites and the charge density there is greater, or there could be a combination of the two effects.

No evidence has therefore been found of positive ions remaining un-neutralized on the surface oxide layers, although if they were responsible for emission from the cathode for a short time, their presence could be masked by emitted electrons and the negative dipole layer. The anode track p.d. suggests that oxide growth effects rather than positive ions are largely responsible for the results.

Any association between the higher arc velocities on second and subsequent runs and the negative dipole layers of the oxide will need further investigation. Suggestions that electron emission can occur from negative ions on oxide layers⁴ have referred to oxide layers of about 1000 Å, and there is no evidence that if oxide thickness is increased on arc tracks it can reach this value.

We thank the Science Research Council for a special grant supporting one of us (K. A. N.). We also thank colleagues for advice.

METEOROLOGY

Determination of Cloud Altitudes from Gemini-Titan-5

DURING the GT-5 manned spacecraft flight mission of August 21-29, 1965, an experiment to determine the cloud top altitude was performed. The instrument used in this experiment has been described by Saiedy *et al.*¹. It is a compact grating spectrograph-camera which records simultaneously a photograph of the cloud and its spectrum from 7500 Å to 7800 Å. Fig. 1 shows a reproduction of one of the 26 observations obtained during the mission. This photograph-spectrogram was taken over a cloudy area in the inter-tropical convergence zone (ITC) at 12° 37' N., 99° 10' W., at 1944:02 G.C.T., August 25.

The principle of deducing cloud-top heights from the absorption by the oxygen 'A' band has been discussed in detail by Wark and Mercer². Briefly, it requires a measurement of the fractional transmittance at a suitable wave-length in this band; the transmittance is determined by the height of the cloud and the local zenith angles of the Sun and the observer. That is, the transmittance depends on the effective amount of oxygen in the optical path above the cloud.

Fig. 2 shows microdensitometer traces of three spectra. The top trace is that of low stratus off Baja, California, at 27° 35' N., 119° 8' W., at 1743:00 G.C.T., August 27. The second trace is taken from the spectrogram shown in Fig. 1. The third trace is that of an observation of tropical storm "Doreen", taken at 20° 8' N., 129° 55' W., at 2120:08 G.C.T., August 24. From the calibration of the film, the transmittances given in Table 1 at selected wave-lengths were deduced. The heights of the cloud tops, calculated from these transmittances and from the solar and observer angles, are also shown in Table 1.

The results were compared with estimated heights for the stratus and with aircraft observations of "Doreen"

Fig. 1. Photograph and spectrogram taken from the GT-5 spacecraft. The spectrogram in the upper part shows the oxygen 'A' band near 7600 Å. The position of the spectrograph slit is outlined in the photograph below. It may be noted that half of the slit is wider than the other in order that a proper exposure could be assured; the effect is apparent in the spectrogram.

Fig. 2. Microdensitometer traces of three spectra obtained by the GT-5 astronauts. The vertical dashed lines are at 7607 Å and 7631 Å, the wave-lengths at which the oxygen transmittances given in Table 1 were calculated.

two days later; no verification is available as yet for the other observation. These preliminary results seem to confirm the most optimistic view of this technique for routine observations from unmanned spacecraft.

Table 1. PRELIMINARY RESULTS OF THREE GT-5 OBSERVATIONS OF CLOUD HEIGHT, DEDUCED FROM TRANSMITTANCES IN THE OXYGEN 'A' BAND. These represent clouds with low, medium and high tops.

Date (August 1965)	Time (G.C.T.)	Cloud identi- fication	Transmittance 7607 Å	7631 Å	Estimated pressure altitude (mbar)	Actual pressure altitude (mbar)
27	1743:00	Stratus	—	0.31	980	960
25	1944:02	I.T.C.	0.39	—	440	—
24	2120:08	"Doreen"	0.51	—	320	(350-220)

Water Balance and Evaporation Studies

PENMAN¹ has put forward an elegant expression for evaporation E for various types of surfaces with a wide range of climatic regions taking into consideration the energy balance and the aerodynamic factors. The equation is:

$$E = \frac{H + Ea \frac{\gamma}{\Delta}}{1 + \frac{\gamma}{\Delta}}, \quad H = R_c(1 - r) - R_B$$

where R_c is incoming radiation, r is the reflexion coefficient for a vegetative surface, R_B is out-going long-wave radiation calculated from:

$$R_B = \sigma T_a^4 \{0.56 - 0.09\sqrt{e_a}\} (1 - \alpha m)$$

σ is the Stefan Boltzmann constant, e_a is the actual vapour pressure and αm is the fraction of sky covered by clouds in tenths.

Ea = aerodynamic term $0.0105(0.5 + 0.01 U) (e_a - e_d)$
 U = miles per day at 2 m height, e_a is the saturation vapour pressure of air at temperature T_a . γ is the psychrometric constant; Δ is the gradient of saturation vapour pressure against temperature curve at air temperature.

The first and last terms in the equation are positive, and contribute positively to evaporation. The term R_B contributes negatively, which means there is condensation taking place due to long-wave radiation. This term assumes a significant role during the night when the incoming radiation is cut off. The evaporation term then consists of two terms, one of which is negative and hence there will in effect be a condensation process taking place. If the aerodynamic term remains unchanged during the night, it contributes to the evaporation a magnitude which may result in the total being negative or positive.

During the winter months on clear-sky days systematic measurements have been made to find the surface soil moisture over Poona. It is found that there is a daily variation of soil moisture, reaching a minimum at the maximum epoch of temperature and a maximum at the minimum temperature epoch. Various explanations have been offered for this variation of moisture. One such explanation is based on the fact that near the surface soil there is a reversal of the vapour pressure gradient at night resulting in invisible condensation.

It appears from Penman's equation that both during day and night there is a process of condensation taking place near the surface of the Earth which in the day is completely outbalanced by the incoming short-wave radiation, resulting in a net evaporation. In the absence of sunlight long-wave radiation plays a predominant part in condensation of water vapour on the soil. This explains also the different moisture-holding capacity of soils under identical meteorological conditions.

Fig. 1. Evaporation from an open water surface at Poona, estimated according to Penman (ref. 1)

In arid and semi-arid zones this factor is important for the study of water balance in relation to crop development in winter and may explain the large vegetation growth during these months when there is no rainfall. A study of the various meteorological factors in contributing to evaporation over Poona using Penman's equation reveals that on an average the annual evaporation is mainly contributed by the term containing the incoming radiation, the sum of other two terms over 52 weeks having equal positive and negative values. The study of evaporation over Poona week by week using Penman's equation shows that about the 16th week and the 40th week, reckoned from January 1 (corresponding to the middle of April and the end of September), the net contribution for evaporation by the aerodynamic term and long-wave radiation term is practically zero. The variation of evaporation with time week by week as calculated by Penman's equation is shown in Fig. 1 and agrees reasonably well with observed open pan evaporimeter values. This investigation will be pursued for all the agrometeorological and crop weather observatories in India where all the parameters required for the calculation of evaporation by Penman's equation are available for more than 10 or 15 years.

CHEMISTRY

Diperoxodiethylenetriamminechromium(IV) 1-hydrate: a New Chromium(IV) Peroxo Compound

DIPEROXOTRIAMMINECHROMIUM(IV), $\text{Cr}(\text{NH}_3)_3(\text{O}_2)_2$, one of the more stable chromium compounds containing peroxo groups¹, has been known for many years², and recently the X-ray crystal structures of this and other chromium peroxo compounds have been reported^{1,3-8}.

We have now prepared an analogous triamine containing the tridentate ligand diethylenetriamine ($\text{NH}_2(\text{CH}_2)_2\text{NH}(\text{CH}_2)_2\text{NH}_2 = \text{dien}$) which crystallizes from water as the 1-hydrate, $[\text{Cr}(\text{dien})(\text{O}_2)_2] \cdot \text{H}_2\text{O}$. The compound was prepared by the dropwise addition of 15 ml. of 30 per cent hydrogen peroxide to a stirred solution of 5 g of sodium dichromate 2-hydrate, 10 ml. of water and 6 ml. of dien at 5°–10°. Effervescence occurred and an orange-brown coloured solution developed due to the formation of the $\text{Cr}(\text{O}_2)_4^{3-}$ anion. The solution was kept at 15° for about two days, the colour slowly changing to lime green and olive-green crystals of $[\text{Cr}(\text{dien})(\text{O}_2)_2] \cdot \text{H}_2\text{O}$ (calc.: Cr, 21.92; C, 20.26; H, 6.37; N, 17.72. Found: Cr, 21.95; C, 20.51; H, 6.34; N, 17.80) were formed. These were collected by filtration and washed with methanol.

The oxidizing power was measured by determining the amount of iodine liberated by the solid from acidified potassium iodide and also by treating the solid with excess permanganate solution, adding excess iron(II) ion and back-titrating with permanganate. The mean of three determinations gave a value of 2.48 moles of iodine per mole of diperoxo complex (theory = 2.50) and 2.95 oxidation equivalents of permanganate per mole of complex (theory = 3.00), supporting the chromium(IV) diperoxo assignment.

The diperoxo complex is soluble in water to give a lime-green solution (λ_{max} 610 m μ ($\epsilon = 38.6 \text{ M}^{-1} \text{ cm}^{-1}$), 520 (41.5), 382 (460), 250 (5,400); λ_{min} 570 (38.5), 485 (38.8), 355 (415), 235 (4,880)) and both the aqueous solution and the solid appear to be stable for at least 24 h at room temperature in laboratory light, although both decompose when warmed. The solid explodes when heated to 109°–110° (heating rate = 2°/min). We have found that

the corresponding water-insoluble aquoethylenediamine ($\text{NH}_2(\text{CH}_2)_2\text{NH}_2 = \text{en}$) analogue^{8,9}, $[\text{Cr}(\text{en})(\text{O}_2)_2(\text{OH}_2)] \cdot \text{H}_2\text{O}$, explodes at 96–97°.

The infra-red spectrum (Nujol mull; Perkin-Elmer model 421) of the new solid shows a strong sharp doublet at 885 and 870 cm^{-1} which is assigned to the —O—O— stretching frequency^{10–12}, and the absence of a strong band in the 930 cm^{-1} region indicates the absence of Cr=O bonding.

Thus there seems little doubt that this stable chromium peroxo compound belongs to Type I of Stomberg's classification¹ (with a geometry probably that of a pentagonal bipyramid, the peroxo oxygen atoms probably being coplanar with the central nitrogen atom of the dien ligand and with the central chromium atom), and that the formal oxidation state of the chromium is +4.

This work was supported by the U.S. Atomic Energy Commission under contract AT(11-1)-34, project 12.

Infra-red Spectra of Quaternary Ammonium Compounds adsorbed on Silica-gel 'Aerosil'

We have examined by infra-red spectrophotometry the reaction of alkyl trimethyl ammonium bromides of chain-length 4–20 with silica surfaces. For these investigations 10^{-2} M solutions of the ammonium compounds were added to 'Aerosil' powder, which had been conditioned by hydration in water at 100° C for 4 h, dried and ignited at 700° C for 72 h, rehydrated as before and finally dried at 120° C. Hockey¹ has shown that this treatment gives a surface containing 4–6 surface silanol groups per 100 Å². Since optimum adsorption was found to occur within the pH range 6.6–8.5, the suspension was adjusted to pH 7 by the addition of 10^{-2} M sodium hydroxide solution. After 2 h the silica plus adsorbate was centrifuged out, dried at 120° C, then pressed into a coherent wafer containing 10–15 mg sample per cm² in a die at 12,000 lb/in.² for 5 min. The wafer was placed in a gas cell, evacuated at a pressure of 10^{-5} mm of mercury for 4 h, and the infra-red spectrum recorded on a Perkin-Elmer 237 double-beam instrument.

Curve B for hexadecyl trimethyl ammonium bromide ($\text{CH}_3(\text{CH}_2)_{15}\text{N}^+(\text{CH}_3)_3\text{Br}^-$) in Fig. 1 is typical of the spectrum obtained for a whole range of compounds. On washing the samples with water, the spectra of the compounds of chain-length <6 revert to that of the original 'Aerosil' (curve A, Fig. 1). For compounds of chain-length 7–20 the spectra are not greatly affected by washing, showing that the compounds are strongly bonded to the silica surface. The particular features of the spectra of the treated silica are the absence of the band at 3,750 cm^{-1} , which in untreated silica is ascribed to free surface silanol groups, and the formation of a new broad band at 3,240 cm^{-1} . (The band at about 2,900 cm^{-1} is from the normal methylene stretching vibrations of the adsorbed molecules.)

Previous workers^{3,4} have postulated a mechanism of attachment for dodecyl trimethyl ammonium bromide from aqueous solutions on silica via cation exchange with surface silanol groups. The present findings do not accord with this since the replacement of the sharp 3,750 cm^{-1}

band by one at 3,210 cm^{-1} is indicative of hydroxyl stretching vibrations in which the normal O—H band has been weakened. On this basis we postulate as a working model the structure:

The complete disappearance of the 3,750 cm^{-1} band suggests that all the surface silanol groups are influenced similarly; but it is not clear from the present evidence whether one quaternary ammonium group is able to react with more than one surface silanol group. Also the possible role of the bromine anion is not elucidated and studies are in hand to check both these points.

General support for this hypothesis is obtained by deuterium oxide exchange. Curve A of Fig. 2 shows the infra-red spectrum of hydrated 'Aerosil' after exposure to deuterium oxide vapour. The 3,750 cm^{-1} band ascribed to —OH stretching is replaced by a similar shaped —OD stretching band at 2,780 cm^{-1} . Likewise curve B for deuterated 'Aerosil' treated with hexadecyl trimethyl ammonium bromide shows that the 'modified' OH band at 3,240 cm^{-1} (see curve B, Fig. 1) is shifted to 2,410 cm^{-1} as expected from simple mass considerations—while the methylene stretching band at about 2,900 cm^{-1} is unaltered as no exchange has occurred.

Finally, we wish to comment on the absorption bands observed at 1,640 cm^{-1} , which has been a matter of contention among many workers, and at 3,660 cm^{-1} . Thompson⁵ has examined the effect of increase in temperature on the

Fig. 1. Comparison of infra-red spectra of 'Aerosil' silica. A, Hydrated to a surface concentration of 4–6 silanol groups per 100 Å; B, as before but treated with 10^{-2} M hexadecyl trimethyl ammonium bromide at pH 7.

Fig. 2. Comparison of infra-red spectra of 'Aerosil' silica. A, Hydrated to a surface concentration of 4–6 silanol groups per 100 Å followed by reaction with deuterium oxide vapour; B, as before but treated with 10^{-2} M hexadecyl trimethyl ammonium bromide at pH 7.

1,640 cm^{-1} band and showed that at 150°C, and at a pressure of 3×10^{-5} mm of mercury, the spectrum showed an absorption apparently equivalent to the background absorption for annealed silica; similar high-temperature treatment has also been found necessary completely to remove the band at 3,660 cm^{-1} . We have compared the spectra of untreated, treated and deuterated silica with ordinate expansion in some cases, and have observed that both the small residual band at 3,660 cm^{-1} (seen clearly in Fig. 2) and the band at 1,640 cm^{-1} (sharply defined in all spectra) are completely unaffected by the deuterium exchange. Although some contribution to the 1,640 cm^{-1} band is undoubtedly due to the harmonic of the SiO vibration, we propose from this evidence that both bands are associated with hydroxyl groups 'trapped' within capillaries or cracks and, therefore, unable to react either with quaternary ammonium compounds or with deuterium oxide.

We thank Dr. J. A. Hockey for his advice.

Inhibition of Corrosion of Copper in Chromic Acid

CORROSION of copper is inhibited in 0.1 N chromic acid of pH 1.6, a loss of 10 mg/dm^2 and no change in appearance is observed after four weeks' immersion. On the other hand, corrosion is significant in sulphuric acid of this pH, and a loss of 150 mg/dm^2 is recorded after an identical period of immersion. This communication describes experiments designed to obtain a fuller understanding of the mechanism by which chromate inhibits the corrosion of copper.

(1) Measurements of electrode potential and film thickness were made on copper chemically polished and left for 3 days in a desiccator over calcium chloride. As shown by the electrometric reduction technique devised earlier¹, specimens treated in this way are covered by a film made up of 14 Å of cuprous oxide and an unidentifiable mixture of copper salts requiring 0.25 mC/cm^2 for reduction.

The results in Table 1 were obtained. These show that the protective power of the oxide film in copper is less in sulphuric acid than in chromic acid.

Table 1

(a) Electrode potential measurements (hydrogen scale)

(i) Copper in 0.1 N sulphuric acid	
On immersion	+0.18 V
After 43 h	+0.20 V
(ii) Copper in 0.1 N chromic acid	
On immersion	+0.65 V
After 43 h	+0.68 V

(b) Oxide film thickness (calculated from a-c bridge measurements at 2,000 c/s using a dielectric constant of 10.5 for cuprous oxide (ref. 2),

(i) In 0.1 N sulphuric acid the apparent film thickness (or approximate thickness of the coherent section of the oxide film adjacent to the metal surface) decreased from 80 Å on immersion to ≤ 50 Å after 43 h.

(ii) In 0.1 N chromic acid the apparent film thickness increased from 22 Å on immersion to 32 Å after 43 h.

(2) An electrometric technique¹ was used to measure film thicknesses on copper which had been stored three days in a desiccator after a treatment comprising chemical polishing³ followed by electrochemical reduction of the

oxide. The cuprous oxide film on the copper surface was ≤ 3.0 Å immediately after this treatment, which increased to 6.0 Å after three days in the desiccator and to 16.0 Å after a further 43 h. Specimens were immersed in test solutions after three days in a desiccator, and left in the solution for 43 h. On removal from the test solution, these specimens were washed with distilled water, rinsed in acetone, and placed in the electrometric cell. The specimens were afterwards immersed in deaerated solution and the nature and thickness of the oxide film were determined (Table 2).

Table 2

- (a) In 0.1 N sulphuric acid, the cuprous oxide film after 43 h immersion was 38 Å thick.
(b) In 0.1 N chromic acid, the film after 43 h immersion was 17 Å thick and no evidence of irreversible adsorption of chromate was obtained.

The results showed the total film thickness to be greater after immersion in sulphuric acid than in chromic acid; however, a.c. bridge measurements indicated that the film thickness decreased in the former solution. Thus it is evident that the film formed in sulphuric acid is porous, and the a.-c. bridge measurements give an indication of the thickness of the coherent or non-porous section of the oxide film.

(3) Measurements of rates of solution of copper from bulk oxide, and oxide-covered copper, were compared and the results are shown in Table 3. Although the anion did not have any significant effect on the rate of solution of bulk oxide, the rate of solution of oxide from the metal surface was markedly decreased in chromic acid.

Table 3

	1 min	1 h	24 h
Concentration of copper, g./ion/l. dissolved from bulk cuprous oxide in 0.1 N H_2SO_4	—	4×10^{-2}	7×10^{-2}
Concentration of copper, g./ion/l. dissolved from bulk cuprous oxide in 0.1 N H_2CrO_4	—	10^{-2}	6×10^{-2}
Concentration of copper, g./ion dissolved from 90 cm^2 in 0.1 N H_2SO_4	3.1×10^{-5}	1.3×10^{-4}	10^{-3}
Concentration of copper, g./ion dissolved from 90 cm^2 copper in 0.1 N H_2CrO_4	3.5×10^{-5}	4.3×10^{-5}	6.4×10^{-5}

These three sets of experiments show that the effect of chromate on copper is to lower the chemical reactivity of the oxide film. The electrometric investigations of copper which had been immersed in chromate solution revealed no evidence of significant irreversible adsorption of chromate. However, when copper was immersed in chromic acid with a ratio of 2.2 ml. solution to 1 cm^2 of metal surface for 1 h, the oxide film stripped from the metal in a mixture of 10 ml. concentrated hydrochloric acid and 10 ml. 1:10 hydrogen peroxide made up to 100 ml. with washings from the specimen and the solution analysed, 2.5×10^{-5} g./ion of chromium was present. These results indicate that chromic ions formed by local electrochemical action had entered the oxide lattice to form a mixed cuprous chromic oxide having a lower chemical activity than the bulk cuprous oxide. It is considered that lowering the chemical activity of the oxide film is the major factor in inhibiting the corrosion of copper in chromic acid.

Effect of Environment on the Orientation of the Nitrate Ions in Crystals

A ROTATIONAL or orientational disorder at room temperature in the arrangement of the nitrate ions has been observed in the crystalline lattices of a number of co-ordination compounds¹⁻⁴, although no one has so far offered any explanation for this phenomenon. The factors

which are known to influence the arrangement of any ionic group in a crystal are the symmetry, the size, and the moment of inertia of the group in question, as well as the nature of packing of various cations and anions. In some cases the charge on the complex cation is completely shielded by neutral groups which surround it, and so the electrostatic interaction with the anionic group is very weak. The net result is that the anion exhibits free rotation. An example of this is provided by the crystal structure of silver perchlorate dioxane complex⁵ in which the perchlorate ion exhibits free rotation.

The factor which has not been considered so far is the influence the nature of the environment has on the orientation of the nitrate ion. The orientation of the nitrate ion (or any other ionic group) in a particular position is effected by those atoms of the surrounding cationic groups, which have a close approach to this group. In all compounds in which the orientation of the nitrate ion is ordered, the symmetry of the environment matches with the symmetry of the nitrate ion. For example, in *tris*-glycine nickel nitrate⁶, every oxygen of the nitrate ion has two hydrogen atoms as neighbours and they are arranged in such a manner that the symmetries of the nitrate ion and its environs match with each other (see Fig. 1). If the nitrate ion in this compound is forced

Fig. 1. Nitrate ion and its environs in the crystal structure of *tris*-glycine nickel nitrate

Fig. 2. 3D projection of the crystal structure of *bis*-dimethylglyoximinodiammine cobalt(III) nitrate, showing the freely rotating nitrate ion and its environs

Fig. 3. Nitrate ion and its environs in the crystal structure of *bis*-adiponitrilo copper nitrate

to rotate, the neighbouring atoms of the environs, which exert an attractive force on the oxygens of nitrate ion, keep this ion in fixed position. All such forces act in the same direction and try to prevent the nitrate ion from exhibiting free rotation.

In all compounds which are known to have disordered arrangement of the nitrate ions, the symmetry of the environment does not match with the symmetry of the nitrate group. In dimethylglyoximinodiammine cobalt nitrate¹, the nitrate ion exhibits free rotation. The environment of this ion has approximately a four-fold symmetry (see Fig. 2). In an arrangement of this type, there are several possible positions for this arrangement of the nitrate ions which correspond to a minimum of the potential energy. Free rotation of this ion then becomes possible since the potential barrier it has to overcome in order to rotate is small under these conditions.

In the crystals of *bis*-adiponitrilo copper(I) nitrate², there is an infinite network of the complex ion $[\text{Cu}(\text{NC}-\text{CH}_2-\text{CN}_2-\text{CN}_2-\text{CH}_2-\text{CN}_2)]_n^{2+}$ and the nitrate ions are located in the gaps of this network (see Fig. 3). The symmetry of the environment of the nitrate ion is four-fold. In this structure, there are four possible arrangements of the nitrate ion which correspond to a minimum of the potential energy. All the four possibilities are present in equal proportions in the crystal structure, which then has an orientational disorder in the arrangement of the nitrate ions.

The crystals of *bis*-glutaronitrilo copper(I) nitrate³ consist of a network of $[\text{Cu}(\text{NC}-\text{CH}_2\text{CH}_2-\text{CH}_2-\text{CN})_2]_n^+$ and the nitrate ion is located in the gaps of this network.

The environment of the nitrate ion has a four-fold symmetry and so the nitrate ion exhibits orientational disorder (see Fig. 4).

The crystal structure of *trans*-dichloro-*bis*-ethylenediammine cobalt(III) nitrate⁴ provides a striking example of the influence which the environment has in producing disorder in the arrangement of the nitrate ions (see Fig. 5). The symmetry of the environment is two-fold, so that in 50 per cent of the unit cells the nitrate ions are nearer to the two carbon atoms of one complex cation and in the remaining cells they are closer to the two carbon atoms of the complex cation. Each of the two arrangements corresponds to a minimum of the potential energy.

A three-dimensional refinement of some of these structures is in progress so that precise information regarding the positions of the nitrate ions and their environs may be obtained in order to discuss the problem in a quantitative manner. In conclusion, it can be stated that by choosing cations and anions of appropriate size, shape and sym-

Ultrasonic Method of Determining the Critical Micelle Concentration of Surfactants

SEVERAL methods¹ are available for measuring the critical micelle concentration in surfactant solutions. An examination of the models of the micelle structure shows that the major concept is that several micellar structures are possible and do exist. The formation of a micelle and each different type of its structure is looked on as that of a new phase. Hence we expected that an examination of ultrasonic velocity at different concentrations in the region of the critical micelle concentration should exhibit a discontinuity in the plot of velocity versus concentration. Sodium dodecyl sulphate at 40° C, cetyl trimethyl ammonium bromide at 35° C, potassium laurate at 35° C and tetrahydroanacardol ammonium monosulphonate at 50° C have been examined. Results obtained are plotted in the graphs (Figs. 1-4).

The solutions were made in conductivity water. The temperature was maintained using a circulating thermostat. Ultrasonic velocity measurements were made at

5 Mc/s using the Debye-Sears² method. The distances between successive diffraction fringes were measured using Hilger's X-ray microphotometer L-486.

From the graphs it is clear that each surfactant shows a reversal in the slope of the velocity versus concentration curve in the region of the critical micelle concentration—the values of the latter given in the literature agree with those shown in the graphs.

In the region in which the ultrasonic velocity falls, the grouping of the surfactant dipoles seems to be occurring

Fig. 1. Tetrahydroanacardol ammonium monosulphonate (50° C)

Fig. 2 Sodium dodecyl (lauryl) sulphate (40° C)

Fig. 3. Cetyl trimethyl ammonium bromide (35°C)

Fig. 4. Potassium laurate (35°C)

progressively through intermediate stages of association. The fall in ultrasonic velocity in the region of micelle formation may be explained on the basis of internal pressure given by the relation:

$$\pi = \frac{T\alpha}{\beta_T} \quad (1)$$

where T is absolute temperature, α and β_T are coefficients of thermal expansion and volume compressibility respectively. At constant temperature, if α is assumed to vary little, the internal pressure π is proportional to $\frac{1}{\beta_T}$:

$$\text{where } \beta_T = \frac{\gamma}{u^2 \rho} \quad (2)$$

where γ is the ratio of specific heats, u the ultrasonic velocity and ρ the density. Assuming ρ to vary very little in this region and γ to be constant, the internal pressure varies as the square of the ultrasonic velocity. Hence in the region of micelle formation there is a heavy fall in internal pressure which perhaps points to either an increase in the free volume⁷ of the medium or a heavy fall in the electrostatic attractive forces or both. Subsequent increase in the ultrasonic velocity after the critical micelle concentration region may have to be explained as due to progressive increase in the electrostatic attractions, or by some mechanism by which the free volume in the medium decreases.

Table 1

No.	Substance	Critical micelle concentration Observed	Literature	Ref.
(1)	Tetrahydroanacardyl ammonium monosulphonate	60-96 mg/l. at 50°C	75-100 mg/l. at 50°C	3
(2)	Sodium dodecyl sulphate	7.11-7.36 mM at 40°C	7 mM at 40°C	4
(3)	Potassium laurate	1.75-2.13 x 10 ⁻² M at 35°C	2.3-2.4 x 10 ⁻² M at 25-8°C	5
(4)	Cetyl trimethyl ammonium bromide	0.87-0.94 mM at 35°C	0.9 mM at 25°C	6

Radiolysis of Sodium Tetrathionate Dihydrate

As part of a study of the radiation chemistry of inorganic sulphur compounds some preliminary results have been obtained for the radiolysis of solid $\text{Na}_2\text{S}_4\text{O}_6 \cdot 2\text{H}_2\text{O}$.

Sodium tetrathionate dihydrate was prepared by making iodine to react with sodium thiosulphate¹. It was purified by repeated precipitation from a warm aqueous solution by the addition of 95 per cent ethanol. Tests indicated that the desired salt had been obtained. The irradiation source was a γ -cell 220 cobalt-60 irradiation unit supplied by Atomic Energy of Canada, Ltd. The dose rates were of the order of 1,200 rads/min. The samples, which were at a temperature of $25^\circ \pm 5^\circ \text{C}$, were irradiated in the presence of air. Samples of the solid salt were irradiated for varying lengths of time and then dissolved in de-aerated triple-distilled water. The resulting solutions were analysed for SO_4^{2-} , $\text{S}_2\text{O}_3^{2-}$, H_2S and acid. Sulphite was found to be absent. The presence of colloidal sulphur was observed. The analytical methods used have been described elsewhere^{2,3}. The amount of substances oxidized by iodine was found by dissolving the samples in an excess of an aqueous solution of iodine and then back-titrating with a standard thiosulphate solution. In Table 1 are given the yields, in μmoles of product/g of irradiated $\text{Na}_2\text{S}_4\text{O}_6 \cdot 2\text{H}_2\text{O}$, of the products for various absorbed doses. Electron spin resonance spectra were used to estimate the number of spins present in the irradiated samples. Electron spin concentrations were measured by graphical double integrations of the recorded spectra and comparison, through a standard of γ -irradiated barium dichloroacetate, with solutions of

Table 1

diphenylpicrylhydrazyl in benzene. The results are included in Table 1.

Experiments using tetrathionate labelled with sulphur-35 were also made to determine the source of the sulphur which appeared in the H_2S . The radioactivity of the H_2S was determined by absorbing it in 'hydramine hydroxide' and then using a liquid scintillation counter^{2,3}. With $\text{Na}_2\text{S}_4\text{O}_6 \cdot 2\text{H}_2\text{O}$ prepared from $\text{Na}_2\text{S}_2\text{O}_3$ labelled in the 'outer' sulphur position (the sulphur linked only to the central sulphur and not to oxygen), the results indicated that 98 per cent of the sulphur in the H_2S originated from a labelled position. Presumably the labelled positions were the two central sulphur atoms of the chain of four sulphur atoms in the $\text{S}_4\text{O}_6^{=}$ ion. The colloidal sulphur formed from the radiolysis of $\text{Na}_2\text{S}_4\text{O}_6 \cdot 2\text{H}_2\text{O}$ labelled as already described here was found to be radioactive. Sodium thiosulphate labelled in the inner sulphur position (the central, oxygen-bonded sulphur atom) was also used to prepare $\text{Na}_2\text{S}_4\text{O}_6 \cdot 2\text{H}_2\text{O}$, the labelled sulphur atoms were presumably the terminal ones of the chain of four sulphur atoms of the $\text{S}_4\text{O}_6^{=}$ ion. The results indicated that 25 per cent of the H_2S sulphur came from the labelled positions, that is, from the oxygen-bonded sulphur atoms of the $\text{S}_4\text{O}_6^{=}$ ion. The reason for the discrepancy of the two sets of results is not known. Considering both sets of results, it appears that at least 75 per cent of the H_2S sulphur comes from the two sulphur atoms in the centre of the chain of four sulphur atoms.

The foregoing results are not sufficient to deduce a very complete mechanism for the radiolysis of $\text{Na}_2\text{S}_4\text{O}_6 \cdot 2\text{H}_2\text{O}$. However, it does seem possible to form some tentative conclusions concerning the mechanism. It appears likely that the two central sulphur atoms of the tetrathionate ion gave rise to the H_2S and the colloidal sulphur produced, whereas the two outer, oxygen bonded, sulphur atoms gave rise to the thiosulphate and sulphate. The results indicate that approximately twice as many $\text{SO}_4^{=}$ ions are produced as are $\text{S}_2\text{O}_3^{=}$ ions. Also the yield of $\text{SO}_4^{=}$ ions is approximately equal to twice the yield of H_2S plus the yield of acid, suggesting that the yield of H^+ is approximately equal to the yield of $\text{SO}_4^{=}$. The following set of reactions is consistent with the foregoing facts:

The water in reactions (2) and (3) would include that present in the solid as water of crystallization as well as that used for dissolving the sample. The water of crystallization would also undergo radiolysis, the products of which could react either with $\text{S}_4\text{O}_6^{=}$ ions or with the postulated intermediates.

No very definite conclusions can be drawn as to the identification of the postulated intermediates. The number of spins observed is only approximately 10 per cent of the number of ions found, hence a large fraction of the intermediates must be other than free radicals. One possibility would be an excited $\text{S}_4\text{O}_6^{=}$ ion which could react with water according to reactions (2) or (3). Since reaction (2) requires the breaking of fewer sulphur-sulphur bonds than does reaction (3), it might be anticipated that the former reaction would be more favoured than the latter. If reaction (2) occurred twice as fast as reaction (3), the observed yield of two $\text{SO}_4^{=}$ ions for each $\text{S}_2\text{O}_3^{=}$ ion would be explained.

It should be noted that reaction (2) results in a ratio of H^+ to $\text{SO}_4^{=}$ which is twice that actually found. It may be, however, that not all the H^+ produced is found since $\text{S}_2\text{O}_3^{=}$ is the anion of a weak acid and the phenolphthalein end-point may correspond to the formation of HS_2O_3^- . If this were so, then the observed yield of H^+ would be in agreement with reactions (1), (2) and (3).

The foregoing tentative mechanism does not account for the formation of any H_2S . The yield of H_2S is less than 10 per cent of the yield of $\text{SO}_4^{=}$ plus $\text{S}_2\text{O}_3^{=}$. It may be that in a small fraction of the reactions of the intermediates with water the central sulphur atoms acquire electrons and appear as $\text{S}^{=}$ ions instead of neutral S atoms as in reactions (2) and (3).

BIOCHEMISTRY

Denaturation of Lactic Dehydrogenase Isozymes and its Clinical Application

It is known that lactic dehydrogenase (LDH) can be inactivated by treatment with various protein denaturants, for example, urea and guanidine hydrochloride^{1,2}. In the denaturing process the tertiary structure of the enzyme is destroyed with the concomitant loss of enzymatic activity. There is evidence that fast-migrating isozyme (LDH_1), a predominant fraction in heart tissue, is less sensitive to these denaturing processes than the slower migrating isozymes^{3,4}. The various isozymes are known to differ from each other in their amino-acid composition and this may play a central part in susceptibility to denaturation.

We have compared the denaturing effect of urea and β -mercaptoethanol on pig heart LDH_1 and rabbit muscle LDH_5 . The effects of urea on human electrophoretically separated LDH_1 and LDH_5 isozymes as well as on the LDH activity of human heart and liver homogenates were determined. The purpose of the work recorded here was to clarify the basis for developing a simple test which would be suitable for clinical detection of the LDH_1 isozyme.

By means of a Beckman DB spectrophotometer at 340 m μ (lightpath 10 mm), the LDH activity was measured in Sørensen phosphate buffer (0.067 M) at pH 7.4 and in a water bath at a temperature of $25 \pm 0.1^\circ\text{C}$. The final concentrations were 2.5×10^{-4} M for pyruvate, 3.3×10^{-3} M for α -ketobutyrate, and 1.3×10^{-4} M for NADH_2 . All determinations were made in duplicate.

Denaturation of LDH_1 and LDH_5 isozymes was measured in various urea and β -mercaptoethanol concentrations following the incubation of buffered enzyme-substrate solution for 10 min at 25°C ; the reaction initiated by means of co-enzyme. Human LDH_1 and LDH_5 isozymes from pooled heart and liver homogenates were prepared by starch-gel electrophoresis modified on the basis of previous reports^{5,6} using phosphate buffer at pH 7.0, from two autopsies about 24 h after death. Individual tissues were homogenized in Sørensen phosphate buffer, pH 7.4, using a Bühler homogenizer. To

minimize the inactivation of the enzyme activity, these procedures were carried out immediately after the tissues were received, and with cooling during the treatment. After electrophoresis the plate was stored overnight at -20°C . Separation of isozyme fractions (1 in. between each fraction) occurred within 6 h. To control the individual content of the various isozyme proportions, agar-gel electrophoresis was performed simultaneously with heart and liver homogenates. Crystalline pig heart LDH_1 and rabbit muscle LDH_5 were purchased from Boehringer and Soehne, Mannheim.

As shown in Fig. 1, urea denaturates electrophoretically separated human LDH_1 to the extent of only about 25 per cent in the concentration used (1.5 M), but brings about denaturation of LDH_5 isozyme to the extent of 90 per cent when the test substrate was pyruvate. The denaturation of the LDE activity of human heart and liver homogenates is slightly greater when concentrations of urea of up to 1.5 M are used; 35 per cent for heart homogenate and 90 per cent for liver at 1.5 M urea. At higher urea concentrations, the denaturation of heart homogenate exceeds that of LDH_1 isozyme, as can be seen by comparing Figs. 1 and 2.

Using a urea concentration of 1.5 M, crystalline LDH_1 (pig heart) was found to bring about a 55 per cent denaturation, while the greatest difference in denaturation between crystalline LDH_1 and LDH_5 from various animals

Fig. 1. Percentage enzymatic activity of human LDH_1 (O) and LDH_5 (●) isozymes separated by starch gel electrophoresis after inhibition with urea at the indicated concentrations. Pyruvate was used as substrate.

Fig. 2. Percentage LDH activity of human heart and liver homogenates after inhibition with urea, pyruvate or α -ketobutyrate as substrate. Heart and pyruvate (O), liver and pyruvate (●), heart and α -ketobutyrate (Δ), and liver and α -ketobutyrate (\blacktriangle).

Fig. 3. The percentage enzymatic activity of crystalline pig heart LDH_1 and rabbit muscle LDH_5 isozymes after inhibition with urea, pyruvate or α -ketobutyrate as substrate. LDH_1 and pyruvate (O), LDH_5 and pyruvate (●), LDH_1 and α -ketobutyrate (Δ), and LDH_5 and α -ketobutyrate (\blacktriangle).

was seen when a urea concentration of 1.25 M was used (Fig. 3).

Human tissue homogenates tested against α -ketobutyrate showed a higher degree of denaturation than when pyruvate was used as substrate (Fig. 2). The same was also observed with crystalline isozymes (Fig. 3).

The electrophoretically separated human isozyme LDH_1 , consisting of monomers B^1 (or H^1), showed much greater resistance to urea denaturation than LDH_5 , consisting of monomers A (or M). The slightly greater denaturation of human heart homogenate compared with the separated human LDH_1 is most probably due to the presence of a small amount of the slower migrating isozymes in the heart tissue. To ensure that electrophoretically separated isozymes were not contaminated with other fractions they were checked by means of agar electrophoresis.

The denaturation of crystalline pig heart LDH_1 with 1.5 M urea was found to be greater (45 per cent) than that of the non-crystalline human heart LDH_1 . This difference might depend on the different degree of purification or on the difference in denaturation susceptibility in various species.

The denaturation of LDH activity of the tissue homogenates as well as of the isozymes tested showed a greater denaturation against α -ketobutyrate than against pyruvate. So it would seem that pyruvate has a stabilizing effect on the enzyme molecule. This is probably because the active centre of the enzyme takes part in the maintenance of the tertiary structure of enzyme molecule. It has also been observed that there is a greater competitive inhibition of LDH fractions by oxamate when α -ketobutyrate was used as substrate than when pyruvate was used⁸. Furthermore, the use of α -ketobutyrate as substrate does not make possible such a clear differentiation between LDH_1 and LDH_5 as does pyruvate, and does not seem so suitable for clinical application. An even more similar denaturation was noted when β -mercaptoethanol was used, with pyruvate as substrate, on crystalline LDH_1 and LDH_5 tested (Fig. 4).

It should be noted that the enzymatic reaction was initiated by means of co-enzyme in order to avoid the formation of enzyme-co-enzyme complex during the incubation. It has been suggested that the formation of this complex would have some effect on the denaturation with various denaturants⁹ and with various co-enzymes^{9,10}. In our preliminary investigations we also noted that NADH₂ may have some effect on the urea denaturation.

We have also tested the denaturing effect of urea (1.5 M) on the LDH activity of added heart and liver

Fig. 4. Percentage enzymatic activity of crystalline pig heart LDH, (O) and rabbit muscle LDH, (●) isozymes after inhibition with β -mercaptoethanol at the concentrations indicated. Pyruvate was used as substrate.

homogenates in normal human serum in order to simulate more closely the situation which arises in myocardial infarction. In these experiments it was verified, by calculation on the base of data observed with homogenates alone, that the degree of denaturation by urea in the serum corresponded with that received. Our observations of denaturation with 1.5 M urea in the conditions described indicate that this technique would be useful for separating the monomers occurring preponderantly in the heart tissue from others for clinical purposes; certainly the test described is simple to carry out.

After we had prepared our communication, Hardy (*Nature*, 206, 933; 1965) published work concerning the denaturation of LDH of human and liver homogenates by urea. The concentration used by him was higher (2.6 M). At this concentration our curves show nearly complete denaturation of all isozymes studied. This difference might well be due to the shorter incubation period used by him. Also the fact that the co-enzyme was added to the incubation solution may contribute to differences in the results.

Ultra-violet Spectroscopy in the Analysis of Chromatograms

THE sensitivity of the normal human eye to light does not extend far below 400 m μ . Nevertheless, ultra-violet-absorbing compounds appear as dark spots on paper chromatograms illuminated with ultra-violet light. This is due to absorption of the light before it can excite the fluorescence of the paper, and constitutes one variety of quenching. Compounds which fluoresce in ultra-violet light will be detected on paper chromatograms if their

fluorescence exceeds that of the surrounding paper. The light sources commonly employed emit the mercury lines at 254 m μ or 366 m μ . In chromatograms of biological extracts the short-wave lamp detects principally the absorbing compounds and the long-wave lamp fluorescing compounds. Beyond this the method possesses little inherent specificity. Thus compounds such as cortisone, nicotinic acid, caffeine and uric acid (λ_{max} 240, 260, 273 and 292 m μ respectively) all appear indistinguishable as dark spots under the short-wave lamp. Furthermore, for substances such as oestrogens, the absorption maximum (280 m μ) of which is very different from the 254 m μ emission of the handlamp, the method is relatively insensitive. A need therefore exists for an instrument with which absorption and activation maxima can be rapidly determined on the paper. I have accordingly designed an ultra-violet spectroscopie in which the ultra-violet light is shifted to the visible region by the fluorescence of either the paper itself or a superimposed screen.

The light source, an 'Osram' 450-W xenon arc, provides an ultra-violet continuum. After passing through a quartz prism monochromator (Schoeffel Instrument Co., Westwood, N.J.) with variable exit slit, the light emerges through a $1\frac{1}{8} \times \frac{3}{4}$ in. rectangular aperture as a slightly divergent beam which illuminates the chromatogram. The latter is attached by spring clips to a frame, which can be moved manually in three planes, or by a motor in the direction of solvent flow only. A screen coated with a suitable phosphor can be placed in position over the illuminated portion of the chromatogram if desired. Among several phosphors examined, $ZnSiO_4:Mn$ and $(Sr, Mg)_3(PO_4)_2:Sn$ were found to be the most generally useful. The former is slightly phosphorescent, but not excessively so. It provides a bright illumination over the range 230–295 m μ and 330–400 m μ . The latter exhibits a continuous though less intense fluorescence over the range 230–370 m μ , and is therefore suitable for rapid, routine searching. To obtain linear wave-length drive the prism is rotated by means of a cam, which is attached to a digital counter. The optical arrangement is shown in Fig. 1, and the assembled apparatus in Fig. 2.

In order to make a visual estimate of the absorption maximum of a compound on a chromatogram, the wave-length knob is rotated until the spot is darkest. The fluorescent screen may be needed to provide adequate background illumination. With certain compounds the maximum is best approached from higher wave-lengths, as the absorption does not always fall off as sharply below the maximum. It is desirable that the brightness of the paper or screen should remain constant while the wave-length of the incident light is varied. To accomplish this a second cam can be used to vary the slit width at different wave-lengths, so as to compensate for changes in the output of the xenon arc, the dispersion of the monochromator, and the spectral response of the paper or screen phosphor.

Fig. 2. The assembled spectroscope

If 'Kodabromide F5' or other suitable photographic paper¹ is placed in contact with the chromatogram, a record of absorbing or fluorescing² compounds can be obtained at any desired wave-length within the operating range of the instrument. If the entire strip is to be photographed the rectangular aperture is replaced by a narrow slit, past which the paper is drawn either by hand or by means of a motor. Arnold *et al.*³ described a similar arrangement for photographing chromatograms, but they used a mercury source, which would only be suitable for observations at certain wave-lengths.

For the determination of the activation spectrum of a fluorescent compound the screen is best avoided, as its fluorescence may mask that of the compound under study. The wave-length knob is rotated until maximal fluorescence is produced. The point at which this occurs will differ slightly from the true activation maximum of the compound, because the intensity of the light issuing from the monochromator increases with wave-length (unless the slit is automatically adjusted by means of a cam). However, a reasonable approximation can be made.

Another application lies in the analysis of thin-layer chromatograms. For this purpose the addition of 10 per cent $\text{ZnSiO}_4 \cdot \text{Mn}$ to the solid phase converts the plate itself into a fluorescent screen. Better contrast is obtained with this technique than with the screen superimposed on a paper chromatogram, which absorbs a significant proportion of the incident light. It was found that quantities of oestrogens which were barely detectable under the 254 m μ handlamp could easily be seen with the spectroscope set at 280 m μ .

The foregoing description has chiefly been concerned with the analysis of compounds on chromatograms. Analogous results can be obtained with compounds in solution in quartz cuvettes. To facilitate the observation of small changes in optical density a reference cell containing the solvent alone is placed alongside the unknown solution. With the aid of the fluorescent screen, absorption maxima can be estimated in exactly the same way as on paper. For example, as little as 2 μg cortisol in 1 ml. absolute ethanol could be spectrally analysed; and the end-absorption of absolute ethanol was discernible below 220 m μ in comparison with a reference cell containing water.

The apparatus can be adapted for automatic scanning of chromatographic strips at a given wave-length, or for recording the absorption spectra of compounds on chromatograms. Modifications of existing spectrophotometers for such purposes have been described by others⁴⁻⁶. The principal advantage of the present technique is that it provides a tool of high sensitivity, permitting the

spectral characteristics of compounds to be studied visually. Furthermore, areas which appear only as streaks on conventional ultra-violet illumination can often be shown by spectroscopy to contain several discrete spots with different absorption or activation maxima. In this way, full advantage can be taken of the high resolving power of the paper or thin-layer chromatogram. These developments have been made possible by the availability of sufficiently intense sources emitting a continuous spectrum in the ultra-violet region.
